Housing Market Responses to Transaction Taxes:
Evidence From Notches and Stimulus in the UK∗

Michael Carlos Best & Henrik Jacobsen Kleven†

February 2016

Abstract

We investigate housing market responses to transaction taxes using administrative data on all property transactions in the UK from 2004-2012 combined with quasi-experimental variation from tax notches and tax stimulus. We present two main findings. First, transaction taxes are highly distortionary across a range of margins, causing large distortions to the price, volume and timing of property transactions. Second, temporary transaction tax cuts are an enormously effective form of fiscal stimulus. A temporary elimination of a 1% transaction tax increased housing market activity by 20% in the short run (due to both timing and extensive responses) and less than half of the stimulus effect was reversed after the tax was reintroduced (due to re-timing). Because of the complementarities between moving house and consumer spending, these stimulus effects translate into extra spending per dollar of tax cut equal to about 1. We interpret our empirical findings in the context of a housing model with downpayment constraints in which leverage amplifies the effects of transaction taxes.

1 Introduction

Transaction taxes on assets are widely discussed but remain understudied (Campbell & Froot 1994; Poterba 2002; Matheson 2011; European Commission 2013). We provide a theoretical and empirical analysis of transaction taxes on housing—a policy that is ubiquitous throughout the world, and raises substantial amounts of revenue in many countries.1 Our empirical analysis focuses on the UK property transaction tax, known as the Stamp Duty Land Tax. The research design relies on administrative stamp duty records on the universe of property transactions in the UK from 2004–2012 combined with rich quasi-experimental variation from notches and stimulus policy. We find that transaction taxes cause large distortions to house prices, transaction volume and timing, and that temporarily cutting such taxes can provide very effective stimulus during recession. Our findings challenge conventional views on the impacts of fiscal stimulus.

Two sources of tax variation are key to our analysis. First, the UK stamp duty features large discontinuities in tax liability—notches—at threshold property prices. For example, the tax rate jumps from 1% to 3% of the entire transaction price at a threshold of £250,000 (about $400,000), creating an increase in tax liability of £5,000 (about $8,000) as the house price crosses this threshold. Such notches create strong incentives for bunching below the threshold, allowing for non-parametric identification of house price responses using bunching techniques (see Kleven 2015 for a review). Second, the UK stamp duty features substantial time variation, including permanent and temporary tax changes that affect specific price brackets but not others. We focus on a stamp duty holiday that lasted 16 months and eliminated transaction taxes in a particular price range in order to provide stimulus to the housing market during the Great Recession. This provides an ideal setting for a difference-in-differences approach to estimating extensive responses (whether or not to buy a house) and timing responses (when to buy a house) to temporary stimulus.

To facilitate interpretation of the empirical results, we develop a theoretical model of housing market responses to transaction taxes. Given our focus on short-run stimulus policy, we consider a setting with a fixed aggregate housing stock in which agents are trading existing houses. A central aspect of housing transaction taxes is that they require large cash payments up front that cannot be financed by borrowing, which may be particularly harmful in a market where agents are liquidity constrained and highly leveraged. Motivated by this observation, our model builds on the seminal housing model with downpayment constraints by Stein (1995). In our model we show that transaction taxes can have large effects on both prices and transaction volumes, especially if there are many downpayment-constrained and highly leveraged households. The intuition turns

---

1As of 2010, 27 countries in the OECD imposed property transaction taxes: Austria, Australia, Belgium, Canada, Chile, the Czech Republic, Denmark, Estonia, Finland, Germany, Greece, Hungary, Ireland, Iceland, Israel, Italy, Japan, the Netherlands, Norway, Poland, Portugal, South Korea, Spain, Sweden, Turkey, the UK, and the US (Andrews et al. 2011). Within the US, 38 states had a property transaction tax in 2012 (Lincoln Institute of Land Policy 2014). Outside the OECD, countries such as Hong Kong, India, Pakistan, and Singapore impose property transaction taxes.
on multiplier effects driven by the fact that transaction taxes reinforce downpayment constraints while the resulting fall in prices reinforces those constraints even further. We argue that this model provides a natural way of rationalizing our empirical findings.

Our empirical findings can be divided into four main categories. First, the distribution of house prices features large and sharp bunching below notch points combined with large holes above notch points. Our bunching estimates imply that house prices respond by a factor of 2–5 times the size of the tax increase at the notch, with larger effects at the bottom than at the top of the price distribution. Bunching in house prices, or rather in the values of transacted houses, represent nominal demand responses rather than price responses per se. As we show, in a world with downpayment constraints, such bunching depends not only on the structural demand elasticity, but also on the amount of leverage among constrained buyers. For example, a downpayment-constrained buyer with a loan-to-value ratio of 75% (the modal value in the UK) will respond by a factor of 4 times the tax increase.\(^2\)

Second, we consider the dynamics of house price responses using both anticipated and unanticipated changes in the location of notches. The dynamic adjustment of bunching and holes to movement of notches is very fast, with a new steady state emerging in about 3–4 months for unanticipated changes and almost immediately for anticipated changes. The remarkable sharpness of our dynamic findings suggests that agents in the housing market are less affected by optimization frictions (inattention, inertia, etc.) than for example agents in the labor market (Chetty et al. 2011; Chetty 2012; Kleven & Waseem 2013; Gelber et al. 2015; Kleven 2015).

Third, we find strong evidence of short-term timing responses to pre-announced tax changes that create time notches at cutoff dates. In the two weeks leading up to an anticipated tax increase, activity levels in the housing market increased by around 150%. Our sharp, non-parametric evidence on timing responses in the housing market contributes to previous findings that short-term timing responses may far exceed medium- or long-run responses (Auerbach 1988; Burman & Randolph 1994; Goolsbee 2000; Einav et al. 2015).

Fourth, we estimate medium-term timing and extensive margin responses to temporary tax changes using the stamp duty holiday. This stimulus program suspended the 1% transaction tax in a specific price range at the lower end of the distribution. We find that the program successfully raised housing market activity as transaction volumes in the treated price range clearly diverged from transaction volumes in untreated price ranges during the holiday. Market activity in the treated price range increased by as much as 20% due to the stimulus. This effect combines a timing effect (intertemporal substitution by those who would have purchased a house anyway) and an extensive margin effect (house purchases that would not have taken place absent the tax holiday). We can separate the two effects by comparing treatments and controls following the removal of the program. Consistent with a timing effect, activity levels in the treatment group dropped by about

\(^2\)In addition, in a world with matching frictions and price bargaining, house price responses to transaction taxes may also be affected by search and bargaining effects (see Best & Kleven 2014; Besley et al. 2014; Kopczuk & Mumroe 2015). There may also be an element of tax evasion and avoidance as we discuss below. Hence, estimating house price responses to taxes is conceptually related to the large literature estimating taxable income responses (see Saez et al. 2012), which combines real labor supply, wage bargaining, evasion/avoidance, etc.
8% compared to the control group in the first year after the holiday, with no further reversal in the second year after the holiday. However, the total reversal effect due to re-timing was less than half of the total stimulus boost, in stark contrast to Mian & Sufi (2012) who find complete reversal within one year of a US stimulus program in the car market.

As in our model, these stimulus effects are most naturally interpreted as increased transactions of existing houses as the aggregate housing stock cannot respond to taxes in the short run. While more trading of existing houses do not add mechanically to GDP, they can have important real effects because trading house typically means moving house.3 Besides the implications of homeowner mobility for housing and labor markets, we highlight that moving house is associated with substantial household spending on repairs, renovations, removals, durable goods, and commissions to agents and lawyers. Using UK consumption survey data, we estimate that a house transaction triggers extra spending of about 5% of the house price. Combined with our estimated increase in transaction volume (20%) and the size of the tax cut (1% of the house price), this implies extra household spending per dollar of tax cut of about 1. This captures only the direct stimulus impact; it does not include any Keynesian multiplier effects. Compared to a large body of evidence on consumer responses to other forms of fiscal stimulus such as tax rebates (e.g. Shapiro & Slemrod 2003a,b; Johnson et al. 2006; Agarwal et al. 2007), our findings suggest that the spending impact of the UK housing stimulus program was considerably larger.

Our stimulus results carry several qualitative lessons that challenge conventional wisdom. (i) The traditional Keynesian view is that tax multipliers are smaller than spending multipliers, because the direct tax multiplier is given by the marginal propensity to consume out of temporary income and is thus significantly smaller than one. In contrast, our findings suggest that transaction tax stimulus may be as effective as spending stimulus, not because the marginal propensity to consume is necessarily high, but because of strong price effects combined with consumption complementarities. (ii) Our paper provides a counter-example to the influential paper by Mian & Sufi (2012), who find complete and swift reversal following the US Cash-for-Clunkers program. This contrast in findings suggests that broad generalizations on the effectiveness of fiscal stimulus cannot be made, and that we have to consider the specific design and implementation of each program. We return to this question later. (iii) While our findings are based on the elimination of a distortionary tax, the insights may apply more broadly to stimulus policies that reduce transaction costs in the housing market (such as the homebuyer tax credit introduced by the US Stimulus Bill of 2009). Moreover, if other fixed costs of housing transactions (such as commissions to real estate agents and lawyers) do not represent only social costs but also rents, there would be a welfare argument for implementing permanent transaction subsidies, the size of which may be adjusted during booms and busts.

We contribute primarily to three literatures. First, we contribute to the voluminous literature attempting to estimate the effects of fiscal stimulus, and especially to recent work that uses micro data to address this question (e.g. Johnson et al. 2006; Agarwal et al. 2007; Mian & Sufi 2012). Our

3Indeed, our empirical analysis focuses on residential property transactions.
analysis of housing investment stimulus has a counterpart in recent work on business investment stimulus from US bonus depreciation policies (e.g. House & Shapiro 2008; Zwick & Mahon 2014). In particular, the finding by Zwick & Mahon (2014) that financially constrained firms (such as small firms with low cash holdings) respond more to stimulus than unconstrained firms is conceptually related to our argument that financially constrained households (those who are downpayment constrained and highly leveraged) respond more strongly to housing stimulus.

Second, our paper belongs to a small body of recent and contemporaneous work studying the effects of property transaction taxes on house prices and homeowner mobility (van Ommeren & van Leuvensteijn 2005; Dachis et al. 2012; Besley et al. 2014; Slemrod et al. 2014; Kopczuk & Munroe 2015). In particular, the contemporaneous papers by Slemrod et al. (2014) and Kopczuk & Munroe (2015) study house price responses using bunching at US tax notches. Unlike these papers, we analyze the dynamics of house price responses, extensive margin responses, timing and stimulus, and so the only real overlap is in the static bunching analysis. Also contemporaneous with this paper, Besley et al. (2014) study the incidence of transaction taxes using the UK stamp duty holiday and mortgage data on house appraisals. None of the earlier literature considers the role of downpayment constraints and leverage for the impact of housing transaction taxes.

Finally, a larger empirical literature has examined the impact of capital gains taxes on asset prices and asset transactions (e.g. Feldstein et al. 1980; Auerbach 1988; Burman & Randolph 1994) and some of this work has focused specifically on the taxation of housing capital gains (Cunningham & Engelhardt 2008; Shan 2011). Transaction taxes and capital gains taxes share the feature that tax liability is triggered by a transaction, with the key difference being that transaction taxes fall on the entire value of the asset and not just on the appreciation of the asset. This difference in tax base is particularly important in the presence of downpayment constraints and high leverage, making behavioral responses to transaction taxes an order of magnitude larger than responses to capital gains taxes, other things equal.

The paper proceeds as follows. Section 2 develops our theoretical model, section 3 describes the context and data, section 4 estimates house price responses using notches, section 5 estimates timing and extensive margin responses to stimulus, and section 6 concludes.

2 Theoretical Framework with Transaction Taxes

This section develops a model to analyze housing market responses to transaction taxes, building on the seminal housing model with downpayment constraints by Stein (1995). Accounting for the downpayment requirements of housing transactions is important in this context, because transaction taxes represent large upfront payments that cannot be financed by debt and therefore reinforce downpayment requirements. We model the effects of transaction taxes on existing homeowners deciding whether to trade their old home for a new one, holding the aggregate housing

---

4 Besides these empirical papers, theoretical work by Lundborg & Skedinger (1999) has analyzed the implications of housing transaction taxes in a search model.
stock fixed. We analyze the impacts of linear and notched transaction taxes at the intensive margin (which house to buy) and the extensive margin (whether or not to buy). We first present a static model that is able to demonstrate the key mechanisms in a parsimonious way, in particular the multiplier effect of transaction taxes in a world with downpayment constrained and leveraged households. We then consider a dynamic generalization that can speak directly to the implications of temporary stimulus policy.\footnote{For the sake of simplicity, we focus on a competitive housing market and therefore abstract from the search frictions that some have argued are significant in the housing market (see, for example, Wheaton 1990; Krainer 2001; Piazzesi & Schneider 2009; Ngai & Tenreyro 2014). In Best & Kleven (2014) we extend the model to allow for matching frictions and price bargaining, but in a version without downpayment constraints.}

### 2.1 Static Model with Downpayment Constraints and Transaction Taxes

Households are endowed with 1 unit of housing and an outstanding debt of $k$ (which we allow to be heterogeneous in the population) denominated in units of a numeraire consumption good. Households can trade houses at a price of $p$ per unit of quality-adjusted housing $h$. If they move house, they sell their existing house, repay their debt $k$, and incur a fixed cost of moving $q$, giving them liquid assets of $p - k - q$. The fixed cost $q$ capture necessary expenditures when moving, including commissions to agents and lawyers. To buy a house of value $v \equiv p \cdot h$, households must make a downpayment of at least $\gamma \cdot v$ financed from their liquid assets, and they can borrow the remainder at an interest rate normalized to 0. They must also pay a transaction tax financed from their liquid assets. As a baseline case, we first consider a linear transaction tax at rate $\tau$. These financing requirements imply that a household can buy a house as long as its value satisfies

$$v \leq \frac{p - k - q}{\gamma + \tau} \equiv v^c. \quad (1)$$

Households choose whether or not to move (extensive margin) and how much housing to buy conditional on moving (intensive margin). After making housing choices, they receive income $1 + k$, repay all debts, and consume their remaining income.\footnote{Setting income equal to $1 + k$ is a convenient normalization that does not affect any of our results.} Letting $c$ denote units of the numeraire consumption good, we consider the following parameterization of preferences

$$u(c, h) = c + A \frac{h}{1 + 1/\varepsilon} \left( \frac{h}{A} \right)^{1+1/\varepsilon}, \quad (2)$$

where $A > 0$, $\varepsilon < 0$ are parameters characterizing housing preferences. The quasi-linear utility function conveniently eliminates income effects on housing demand as we will focus purely on the price effect.\footnote{While we do not make use of this assumption in our empirical analysis, the presence of income effects implies that our bunching estimates should be interpreted as reflecting a combination of income and substitution effects (Saez 2010; Kleven & Waseem 2013; Kleven 2015).}

Households thus maximise utility (2) subject to the downpayment constraint (1) and the budget constraint.
\[ c = 1 + I_m \cdot (p \cdot [1 - (1 + \tau) h] - q) , \]  

where \( I_m \) is an indicator for moving.\(^8\) We allow for heterogeneity in all parameters captured by a smooth density distribution \( f(A, \varepsilon, \gamma, q, k) \). Conditional on moving \((I_m = 1)\), household optimization yields a housing demand function

\[ h^* = \min \{ h^u, h^c \} = \min \{ A((1 + \tau) p)^\varepsilon, v^c / p \} , \]

where \( h^u = A((1 + \tau) p)^\varepsilon \) is unconstrained housing demand and \( h^c = v^c / p \) is constrained housing demand. This specification implies that housing demand elasticities are very different in the constrained and unconstrained states. The unconstrained elasticity with respect to \((1 + \tau) p\) is given by the structural parameter \( \varepsilon \). The constrained elasticities with respect to taxes \( 1 + \tau \) and prices \( p \), respectively, are equal to \( \varepsilon^c_\tau \equiv \frac{\partial h^c}{\partial \tau} \cdot \frac{1 + \varepsilon}{h^c} = -\frac{1 + \tau}{\gamma + \tau} < 0 \) and \( \varepsilon^c_p \equiv \frac{\partial h^c}{\partial p} \cdot \frac{p}{h^c} = -\frac{k + q}{(\gamma + \tau)v^c} > 0 \). Hence, the constrained elasticities with respect to taxes and prices have opposite signs, reflecting the fact that higher transaction taxes reinforce downpayment constraints while higher prices relax them.

A household is downpayment constrained whenever \( h^u > h^c \). This happens when it has too much debt (and thus insufficient liquidity) to meet the downpayment on its preferred house, i.e. when

\[ k > p \cdot [1 - A \cdot [(1 + \tau) p]^\varepsilon \cdot (\gamma + \tau)] - q \equiv k_1 , \]

Note that the threshold debt level \( k_1 \) varies with household type \((A, \varepsilon, \gamma, q)\) as well as with taxes and prices. Downpayment constrained households for whom \( k > k_1 \) will still move if they can afford a house that gives them higher utility than their current house. This will be the case whenever debt \( k \leq k_2 \) where \( k_2 \) satisfies

\[ u \cdot (1 + p - (1 + \tau) \cdot v^c(k_2, \gamma, q, p, \tau) - q, v^c(k_2, \gamma, q, p, \tau) / p) = u(1, 1) . \]

This defines a second threshold debt level \( k_2 \) that varies with household type, taxes and prices.

Even for households that are not liquidity constrained, the utility gain from moving to their preferred house may be outweighed by the utility loss from transaction taxes and fixed moving costs. This creates a standard extensive margin effect of taxes on moving, sometimes referred to as a lock-in effect. Such lock-in happens when

\[ u \cdot (1 + p - (1 + \tau) \cdot ph^u - q, h^u) < u(1, 1) \]

\[ q > p - A \cdot [p \cdot (1 + \tau)]^{1+\varepsilon} \cdot \frac{A^{-1/\varepsilon}}{1 + 1/\varepsilon} = \hat{q} \]

Note that for some household types, \( \hat{q} < 0 \). These households’ preferred house is so similar to

\(^8\)In the budget constraint (3), it is implicitly assumed that the house value depreciates to zero at the end of life. This is a common simplification in finite horizon housing models (e.g. Stein 1995) and entails no loss of generality for the qualitative mechanisms we study here. If we allow for any arbitrary rate of depreciation \( \delta \), the budget constraint would read \( c = 1 + (1 - I_m) \cdot (1 - \delta) p + I_m \cdot p \cdot [1 - (\delta + \tau) h - q] \), which simplifies to equation (3) for \( \delta = 1 \).
their current house that even without any fixed cost, the transaction tax is sufficient to deter them from moving. Note also that, while \( \bar{q} \) is defined for unconstrained households, the threshold also applies to constrained households: equations (5)-(7) imply that whenever \( q \gtrsim \bar{q} \) we have \( \bar{k}_2 \gtrsim \bar{k}_1 \), and so there exists no positive interval of constrained movers above the fixed cost threshold \( \bar{q} \).

To summarize the model thus far, we have three sets of households depending on their initial debt levels \( k \) and their fixed costs \( q \). First, there are unconstrained movers whose initial debt level is small enough that they are not downpayment constrained \( (k \leq \bar{k}_1) \) and who face small fixed costs \( (q \leq \bar{q}) \). These households move to their preferred house. Second, there are constrained movers whose initial debt level makes them downpayment constrained, but who still find it worthwhile to move \( (\bar{k}_1 < k \leq \bar{k}_2 \) and \( q \leq \bar{q}) \). These households move to the best house they can afford given their liquidity. Finally, non-movers choose to remain in their current house, because they have such high debt levels that the new house they can afford is worse than staying in their current house \( (\bar{k}_2 < k) \) and/or because they face high fixed costs \( q > \bar{q} \).

Each mover sells their existing house (1 unit) and buys a new house as characterized above. An equilibrium in this market requires that aggregate excess demand \( D \) equals zero, i.e.

\[
D = \int_A \int_\varepsilon \int_\gamma \int_0^{\bar{q}} \left[ \int_0^{\bar{k}_1} (h^e - 1) f(\cdot) + \int_{\bar{k}_1}^{\bar{k}_2} (h^c - 1) f(\cdot) \right] \, dk \, dq \, d\gamma \, dz \, dA = 0. \tag{8}
\]

2.2 Effects of a Linear Transaction Tax

We start by characterizing the effects of a linear transaction tax in partial equilibrium, i.e. taking the price level \( p \) as given. The transaction tax has three effects on the housing market as summarized in the following proposition:

Proposition 1 (Effects of Transaction Tax in Partial Equilibrium). A change in the transaction tax rate \( \tau \) has three effects on the housing market:

(i) an intensive margin effect as households who move demand less housing: \( dh^*/d(1+\tau) < 0 \);

(ii) a liquidity constraining effect as the share of individuals who are downpayment constrained increases: \( d\bar{k}_1/d(1+\tau) < 0 \);

(iii) an extensive margin effect as fewer households move: \( d\bar{k}_2/d(1+\tau) < 0 \) and \( d\bar{q}/d(1+\tau) < 0 \).

Proof. (i) follows from differentiation of (4), as captured by the elasticities \( \varepsilon \) & \( \varepsilon^c \) defined above. (ii) follows from differentiation of (5), and (iii) from implicit differentiation of (6) and (7).

We now consider how leverage (as captured by the loan-to-value ratio \( 1 - \gamma \)) amplifies demand responses to transaction taxes. This can be characterized as follows:

Proposition 2 (Interaction Between Leverage and Transaction Tax in Partial Equilibrium). Leverage \( 1 - \gamma \) amplifies both intensive and extensive margin responses among downpayment constrained households. In particular,

(i) Intensive margin responses are larger the more leveraged households are: \( d^2 h^c/d(1+\tau) d(1-\gamma) < 0 \).

(ii) Extensive margin responses are larger the more leveraged households are: \( d^2 \bar{k}_2/d(1+\tau) d(1-\gamma) < 0 \).
Proof. To see (i), observe that for downpayment constrained buyers, the housing demand response to a tax increase equals \( \frac{dh^c}{d(1+\tau)} = -\frac{h^c}{\gamma + \tau} \) and differentiating, \( \frac{d^2h^c}{d(1+\tau)d(1-\gamma)} = -\frac{2h^c}{(\gamma + \tau)^2} < 0 \). To see (ii), note that implicitly differentiating (6) yields \( \frac{dk_2}{d(1+\tau)} = -\varepsilon \left[ \frac{(1-\gamma)p - \left( \frac{h^c}{\tau} \right)^{1/\varepsilon}}{(1+\tau)p - (\frac{h^c}{\tau})^{1/\varepsilon}} \right] < 0 \). When signing this derivative we use that both the numerator and denominator in the term in square brackets are negative for a downpayment constrained household since their housing consumption is below their unconstrained optimum. Differentiating again, we can obtain the following result

\[
\frac{d^2k_2}{d(1+\tau)d(1-\gamma)} = \frac{1}{\gamma + \tau} \cdot \frac{dk_2}{d(1+\tau)} - \varepsilon p \left( \frac{1+\tau}{(1+\tau)p - (\frac{h^c}{\tau})^{1/\varepsilon}} \right)^2. 
\]

The first term of this derivative is always negative, and the second term is also negative except for extreme values of the unconstrained demand elasticity \( \varepsilon \) (making the second term zero requires \( \varepsilon \) sufficiently below -1, in which case the full derivative is still negative, so making the full derivative positive would require extreme values of \( \varepsilon \)).

Proposition 2 implies that small transaction taxes can generate large behavioral responses amongst liquidity constrained and leveraged households even if the unconstrained demand elasticity \( \varepsilon \) is modest. For the intensive margin responses, this can be seen directly from the constrained demand elasticity defined earlier, \( \varepsilon^c \equiv -\frac{1+\tau}{\gamma + \tau} \). This implies that a household with a loan-to-value ratio of 75% (the modal value in the UK in our sample period, see Financial Conduct Authority 2014) would have an elasticity of approximately 4 in absolute value, much larger than what might be a reasonable value for the unconstrained elasticity \( \varepsilon \). Similarly, extensive margin responses are stronger for more leveraged buyers. For highly leveraged buyers, even small changes in the transaction tax are leveraged into large changes in the house that they can afford, and so can have large impacts on transaction levels in the housing market.

The demand effects characterized above change excess demand in the housing market and thus lead to price changes to satisfy the equilibrium condition (8). In a standard perfect market model with fixed housing supply, there would be full pass-through of taxes onto prices such that the after-tax price \( (1+\tau)p \) and demand would be completely unaffected by taxes in market equilibrium. However, this classic benchmark result does not necessarily hold in a model with moving frictions due to downpayment constraints and fixed moving costs. In this model the effect of transaction taxes on house prices can be characterized as follows:

**Proposition 3 (Effect of Transaction Tax on House Prices in General Equilibrium).** Denoting the share of unconstrained movers by \( U \), the share of constrained movers by \( C \), and the share of all movers by \( M = U + C \), the elasticity of the house price with respect to \( 1+\tau \) can be written as

\[
\frac{dp}{p} \left/ \frac{d\tau}{1+\tau} \right. = \frac{U \cdot E\{\varepsilon h^u | U\} + C \cdot E\{\varepsilon^c h^c | C\} + M \cdot E\{\eta^k_x (h^c - 1) + \eta^m_x (h^u - 1)\}}{U \cdot E\{\varepsilon h^u | U\} + C \cdot E\{\varepsilon^c h^c | C\} + M \cdot E\{\eta^k_x (h^c - 1) + \eta^m_x (h^u - 1)\}}, 
\]

where we define \( \eta^k_x \equiv \int_0^\varphi \frac{dk_2}{dx} f(A, \varepsilon, \gamma, q, k) \frac{x}{\int_0^\varphi \int_0^\varphi \int_{\varphi} f(A, \varepsilon, \gamma, q, k) dk dq} \) as the extensive margin elasticity of moving for downpayment-constrained buyers (for a specific type \( A, \varepsilon, \gamma \)) with respect to \( x = p, 1+\tau, \ldots \)}.
and \( \eta^q \equiv \int_0^{k_2} \frac{dq}{dx} f(A, \varepsilon, \gamma, \bar{q}, k) \int_0^{k_2} \frac{x}{\int_0^{k_2} f(A, \varepsilon, \gamma, q, k) dq} \) as the extensive margin elasticity for fixed-cost constrained buyers with respect to \( x \).

**Proof.** Implicit differentiation of the equilibrium condition (8) gives \( \frac{dp}{d\tau} = -\frac{dD}{d\tau} \frac{dD}{dp} \). Using the household demand conditions (1), (4), (5), (6) and (7), the definitions of the intensive and extensive margin elasticities, the definitions of the population shares \( U, C, M \), and rearranging terms, it is possible to write the elasticity of equilibrium prices with respect to taxes in the form (9).

This result provides an intuitive, sufficient-statistics characterization of tax incidence in housing markets with downpayment constraints. The formula is based on a set of demand-weighted average elasticities at the intensive and extensive margins. The extensive margin elasticities for downpayment-constrained and fixed-cost constrained buyers are weighted by \( h^c - 1 \) and \( h^u - 1 \), respectively, because these are the contributions to excess demand by the two types of movers. To understand equation (9), it is instructive to start by considering the perfect market case without downpayment constraints (\( \gamma = 0 \)), transaction taxes (\( \tau = 0 \)), or fixed costs of moving (\( q = 0 \)). In this case there are no constrained movers (\( C = 0 \)), no extensive margin responses due to liquidity constraints (\( \eta^k \gamma, \eta^k p = 0 \)), and no extensive margin responses due to fixed moving costs (\( \eta^q \tau, \eta^q p = 0 \)). As a result, equation (9) reduces to \( -\frac{dp/p}{d\tau/(1+\tau)} = -1 \), i.e. the standard incidence result in a world with fixed supply. The simple reason for the standard result is that, for demand to be unchanged in equilibrium, it must be the case that \( (1 + \tau)p \) is unchanged. This changes in a world with downpayment constraints, because now constrained movers react very differently to prices and taxes due to the fact that one relaxes downpayment constraints and the other reinforces them.

It is interesting to consider the role of the second term in the numerator and denominator, respectively, i.e. the intensive margin demand effects of prices and taxes on the constrained movers. The effect of prices on the constrained movers (second term in the denominator) is positive: higher prices increase demand by relaxing downpayment constraints. This effect was precisely the focus of the seminal Stein (1995) paper, but in a different context than tax incidence. Other things equal, this effect tends to offset the standard demand effect (first term in the denominator) and make aggregate excess demand less sensitive to prices. At the same time, the effect of transaction taxes on the constrained movers (second term in the numerator) is negative: higher taxes reduce demand by reinforcing downpayment constraints. This reinforces the the standard demand effect (first term in the numerator) and makes aggregate excess demand more sensitive to taxes. These two effects combined make prices more sensitive to taxes, potentially by a lot if there are many constrained and highly leveraged households. The basic intuition is that higher taxes reduce demand by more in the presence of liquidity constraints, while lower prices are less effective at getting de-

---

As this incidence result is based on \( \tau = 0 \), it represents the incidence of small transactions taxes. The reason why we need to start from \( \tau = 0 \) to obtain full pass-through (whereas in standard models with fixed supply, full pass-through holds for any \( \tau \)) is that in our model transaction taxes create liquidity constraints. Furthermore, the reason why we also need \( q = 0 \) to obtain full pass-through is that otherwise the widespread extensive margin elasticities with respect to taxes and prices, respectively, are different: \( \eta^q \neq \eta^q \). This difference arises because in our model, higher house prices have a positive wealth effect on movers but not on stayers (as the house depreciates to zero at the end of life) which makes \( \bar{q} \) depend differently on taxes and prices as shown by equation (7).
mand back up. The end result is also affected by the extensive margin terms, the signs of which are ambiguous depending on whether marginal movers sell more or less housing than they buy, but the intensive margin terms create the possibility of strong leverage multiplier effects that make prices excessively sensitive to taxes.

Importantly, while the strong price responses discussed above re-establish equilibrium in the housing market, they do not undo the effect of transaction taxes on transaction levels (i.e., the number of movers with \( k \leq \bar{k}_2 \) and \( q \leq \bar{q} \)) and may actually reinforce them. The reason is that lower prices may reduce the number of constrained movers (as \( dk_2/dp > 0 \)) by relaxing downpayment constraints. This implies potentially strong multiplier effects of transaction taxes on transaction volume: higher taxes directly reduce transaction levels (more so if leverage \( 1 - \gamma \) is high) in response to which prices fall and potentially reduce transaction levels even further (and again, more so if leverage \( 1 - \gamma \) is high). Hence transaction taxes can have very large effects on both prices and transaction volumes in the housing market, consistent with our empirical findings below.

2.3 Effects of a Notched Transaction Tax

Now consider the introduction of a discrete jump \( \Delta \tau \) in the transaction tax rate—a notch—at a threshold property value \( \bar{v} \). The notched tax schedule can be written as \( T(v) = \tau \cdot v + \Delta \tau \cdot v \cdot I\{v > \bar{v}\} \) where \( I\{\cdot\} \) is an indicator for being above the threshold.

Figure 1 illustrates the implications of this notch in budget set diagrams for different levels of initial debt \( k \) (panels A–C) and a density distribution diagram (panel D). Each budget set diagram (depicted in \((v, c)\)-space) illustrates intensive margin responses among households with heterogeneous housing preferences \( A \), but a specific demand elasticity \( \varepsilon \) and specific values of \( \gamma, q, \) and \( k \). The notch creates bunching at the cutoff \( \bar{v} \) by all households in a preference range \( (\bar{A}, \bar{A} + \Delta \bar{A}) \), who would have bought houses on the segment \((\bar{v}, \bar{v} + \Delta \bar{v})\) in the absence of the notch. The marginal bunching household at \( \bar{A} + \Delta \bar{A} \) is indifferent between the notch point \( \bar{v} \) and the best interior location \( v_I \). No household is willing to locate between \( \bar{v} \) and \( v_I \), and hence this range is completely empty.\(^{10}\)

The initial debt level affects whether or not the marginal bunching household is downpayment constrained in the counterfactual location \( \bar{v} + \Delta \bar{v} \) without the notch, at the best interior location \( v_I \) with the notch, or in both locations. As we analyze in appendix B.1, this affects whether we interpret bunching as identifying the unconstrained demand elasticity \( \varepsilon \) or as a combination of \( \varepsilon \) and the effect of downpayment constraints, in which case bunching only identifies bounds on \( \varepsilon \). Panel A depicts households with low levels of \( k \).\(^{11}\) The marginal bunching household in this

\(^{10}\)Notice that the above characterization is based on a given price \( p \) per unit of housing. The change in excess demand due to the notch will affect the equilibrium price, which by itself will shift indifference curves in Panel A (as they are depicted in \((v, c)\)-space) and hence shift the density distribution of house values. The qualitative characterization above holds for any arbitrary price and therefore also for the new equilibrium price. The key insight is that, in this competitive model, price incidence occurs at the market level and therefore does not contribute to bunching and holes locally around notches. Best & Kleven (2014) considers a bargaining model where price incidence occurs at the match level in which case price incidence does create bunching and holes.

\(^{11}\)More precisely, for these households we have \( k \leq p \left[ 1 - A \left( (1 + \tau + \Delta \tau) p \right]^\varepsilon \left( \gamma + \tau + \Delta \tau \right) \right] - q \)
Extensive responses converge to zero just above the cutoff as indifference between buying and not buying, i.e. \( q \). Here the marginal bunching household is downpayment constrained at the best interior location \( v^f \) in the presence of the notch, but not in the counterfactual scenario at \( \bar{v} + \Delta \bar{v} \). As shown in appendix B.1, in this case bunching can be used to identify bounds on the structural parameter \( \varepsilon \). Finally, when initial debt levels are high, the marginal bunching household is downpayment constrained both at its best interior location \( v^f \) and at the counterfactual location \( \bar{v} + \Delta \bar{v} \) as depicted in panel C. In this case, bunching only identifies an upper bound on the parameter \( \varepsilon \).

In addition to intensive responses, the notch creates extensive responses above the threshold by households close to being indifferent between buying and not buying. Among downpayment-constrained households there will be extensive responses by those with \( k < (\bar{k}_2 - \Delta \bar{k}_2, \bar{k}_2) \). However, such extensive responses will be negligible just above the cutoff, i.e. \( \Delta \bar{k}_2 = 0 \) when \( v \approx \bar{v} \). This can be seen by considering a household who prefers a location on the segment \((\bar{v}, \bar{v} + \Delta \bar{v})\) without the notch and therefore prefers \( \bar{v} \) with the notch (conditional on moving). For this household the notch reduces the utility from moving by \( \Delta u = u(1 + p - (1 + \tau) v^c - q, v^c/p) - u(\bar{c}, \bar{v}/p) \), where \( \bar{c}, \bar{v}/p \) is the consumption bundle obtained at the notch. As the preferred point absent the notch \( v^c \) converges to the cutoff \( \bar{v} \) from above (and hence \( 1 + p - (1 + \tau) v^c - q \) converges to \( \bar{c} \)), \( \Delta u \) converges to zero and hence the extensive margin decision in unaffected. Intuitively, if in the absence of the notch a household buys a house slightly above \( \bar{v} \), then in the presence of the notch it will be better off buying a house at \( \bar{v} \) (which is almost as good) rather than not buying at all. While we made this argument for extensive responses due to downpayment constraints, an analogous argument implies that extensive responses due to fixed costs (by those with \( q \in (\bar{q} - \Delta \bar{q}, \bar{q}) \)) also converge to zero just above the cutoff \( (\Delta \bar{q} = 0 \text{ when } v \approx \bar{v}) \). Combining all the above reasoning implies that intensive and extensive responses affect the density distribution as illustrated in panel D in which we allow for heterogeneity in all the parameters \( A, \varepsilon, \gamma, q, k \). These effects can be summarized in the following proposition

**Proposition 4 (Effects of Transaction Tax Notches).** A transaction tax featuring a notch at a property value \( \bar{v} \) at which the proportional tax rate jumps from \( \tau \) to \( \tau + \Delta \tau \) induces

**(i)** intensive margin responses as agents in a house price range \((\bar{v}, \bar{v} + \Delta \bar{v})\) bunch at the threshold \( \bar{v} \), where the width of the bunching segment \( \Delta \bar{v} \) depends on both the unconstrained demand elasticity \( \varepsilon \) and downpayment constraints; and

**(ii)** extensive margin responses as agents in the house price range \((\bar{v}, \infty)\) who are sufficiently close to indifference between buying and not buying, i.e. \( q \in (\bar{q} - \Delta \bar{q}, \bar{q}) \) or \( k \in (\bar{k}_2 - \Delta \bar{k}_2, \bar{k}_2) \), no longer buy. Extensive responses converge to zero just above the cutoff as \( \Delta \bar{q}, \Delta \bar{k}_2 \to 0 \) for \( v \to v^* + \tau \).

---

12Specifically, for these households we have \( p[1 - A[(1 + \tau + \Delta \tau) + p]^\varepsilon (\gamma + \tau)] - q < k \leq p[1 - A[(1 + \tau) + p]^\varepsilon (\gamma + \tau)] - q \). For this range of \( k \) to exist (i.e., for the upper bound to be larger than the lower bound) it has to hold that whenever the marginal bunching household is downpayment constrained absent the notch, they are also downpayment constrained at the interior location in the presence of the notch. This corresponds to an assumption that the unconstrained elasticity \( \varepsilon \) is not too large in absolute value.

13That is, whenever \( k > p[1 - A[(1 + \tau) + p]^\varepsilon (\gamma + \tau)] - q \).
These effects imply that at the threshold $\bar{v}$ the density of house values features an excess mass of

$$B(\bar{v}) = \int_{\bar{v}}^{\bar{v} + \Delta \bar{v}} g_0(v) \, dv \approx g_0(\bar{v}) \Delta \bar{v},$$  

(10)

where $B(\bar{v})$ is excess bunching and $g_0(v)$ is the counterfactual density of house values (the density that would prevail absent the notch). The approximation assumes that the counterfactual is roughly uniform around the notch. Based on equation (10), it is possible to recover the house price response $\Delta \bar{v}$ based on estimates of the counterfactual distribution $g_0(v)$ and bunching $B(\bar{v})$.

The relationship (10) implicitly assumes that there is just one bunching segment $(\bar{v}, \bar{v} + \Delta \bar{v})$, which amounts to assuming that $\varepsilon, \gamma, q$ and $k$ are homogeneous in the population. Our model allows for heterogeneity and we can also account for it in the empirical implementation. There will be a price response $\Delta \bar{v}(\theta)$ and a counterfactual density $\tilde{g}_0(v, \theta)$ associated with each type $\theta \equiv \{\varepsilon, \gamma, q, k\}$. In this case, equation (10) can be generalized to

$$B(\bar{v}) = \int_{\theta} \int_{\bar{v}}^{\bar{v} + \Delta \bar{v}(\theta)} \tilde{g}_0(v, \theta) \, dv \, d\theta \approx g_0(\bar{v}) E[\Delta \bar{v}],$$  

(11)

where $E[\Delta \bar{v}]$ is the average house price response across all types $\theta$ around the threshold $\bar{v}$. As before, the approximation requires that the counterfactual density is locally uniform in house prices $v$ (but not in type $\theta$) around the threshold. Equation (11) shows that, in the presence of heterogeneity, estimates of the counterfactual distribution and bunching allow us to recover the local average response.

### 2.4 Dynamic Model and the Effects of Temporary Tax Changes

To guide the empirical analysis of temporary stimulus policy, let us consider a dynamic extension of the previous model. In general, temporary tax changes will create both timing responses and extensive margin responses in the housing market. To see this, consider a simple two-period extension of the model in which agents maximize lifetime utility $u_1(c_1, h_1) + \delta u_2(c_2, h_2)$ where the per-period utility functions are given by

$$u_t(c_t, h_t) = c_t + \frac{A_t}{1 + 1/\varepsilon_t} \left( \frac{h_t}{A_t} \right)^{1+1/\varepsilon_t}, \quad t \in \{1, 2\}.  

(12)$$

Households enter period 1 with one unit of housing and $k_1$ units of debt. If they decide to move, they sell their house at the prevailing price $p_1$, repay their debt, and incur a fixed cost $q_1$ giving them liquid assets $p_1 - k_1 - q_1$. As in the static model, they must finance a downpayment of $\gamma_1 v_1$ and a transaction tax of $\tau_1 v_1$ out of their liquid assets, and so they can buy any house satisfying the period-1 liquidity constraint $v_1 \leq (p_1 - k_1 - q_1) / (\gamma_1 + \tau_1) \equiv v_1^c$. Housing and consumption decisions in period 1 must also satisfy the budget constraint

$$c_1 = y_1 - s_1 + I_{m_1} \cdot [p_1 - k_1 - q_1 - (\gamma_1 + \tau_1) v_1],  

(13)$$

12
where $I_{m_1}$ is an indicator for moving in period 1 and $s_1$ denotes financial savings. Note that while the quasi-linear formulation of preferences eliminates the standard consumption-smoothing motive to save, households may still wish to save to relax future liquidity constraints. If a household moves in period 1, its outstanding mortgage debt equals $v_t(1 - \gamma_1)$, while otherwise it equals $k_1$. The household’s net debt carried forward to period 2 is therefore given by $k_2 = k_1 + I_{m_1} \cdot v_t(1 - \gamma_1) - k_1 - s_1$. Denoting the gross interest rate by $R = 1/\delta$, households enter period 2 with $Rk_2$ units of debt.

Households face a similar housing choice in period 2, but enter the period with $h_1$ units of housing (where $h_1 = 1$ if they did not move in period 1). If they move in period 2, they will have liquid assets $p_2h_1 - Rk_2 - q_2$ with which to finance a downpayment of $\gamma_2v_2$ and a transaction tax of $\tau_2v_2$. Hence the period-2 liquidity constraint requires $v_2 \leq (p_2h_1 - Rk_2 - q_2) / (\gamma_2 + \tau_2) \equiv v_2^\ast$. The period-2 budget constraint is given by

$$c_2 = y_2 - Rk_2 + I_{m_2} \cdot (p_2 [h_1 - (1 + \tau_2)h_2] - q_2).$$

(14)

We normalize $y_2 = Ry_1$ and $y_1 = (1 + k_1)/2$ for convenience.\footnote{This normalization implies that the income streams of all households with initial debt $k_1$ are the same. Relaxing these would require us to keep track of the NPV and time profile of households’ income when studying their housing decisions, adding complexity without changing any of the qualitative conclusions. Notice also that, as in the static model, we assume that income in both periods $y_1, y_2$ is received after making housing and consumption decisions, which is the reason why current income does not relax current liquidity constraints (but of course does relax future liquidity constraints, other things equal, through its effect on $s_1$ and thus $k_2$).}

Solving the model backwards, period 2 operates in the same way as the static model in section 2.2. Conditional on moving, households demand housing $h_2^\ast = \min \{h_2^u, h_2^\ast\}$ where $h_2^u = A_2 ((1 + \tau_2) p_2)^{\epsilon_2}$ and $h_2^\ast = v_2^\ast/p_2$. Households will therefore move in period 2 whenever

$$u_2(c_2^\ast, h_2^\ast) \geq u_2(y_2 - Rk_2, h_1),$$

(15)

where $c_2^\ast = y_2 - Rk_2 + p_2 [h_1 - (1 + \tau_2)h_2^\ast] - q_2$. For each household type, condition (15) implicitly defines threshold levels for period-2 debt $k_2^\ast$ (when considering (15) with equality for downpayment-constrained households) and for period-2 fixed costs $\tilde{q}_2$ (when considering (15) with inequality for unconstrained households), below which households choose to move. We can write their indirect utility in period 2 as a function of the things they chose in the previous period: $V(h_1, Rk_2) \equiv \max \{u_2(c_2^\ast, h_2^\ast), u_2(y_2 - Rk_2, h_1)\}$.

In period 1, households anticipate the effect that their housing and saving choices will have on their utility in period 2, and so they maximize $u_1(c_1, h_1) + \delta V(h_1, Rk_2)$ subject to their period-1 budget and liquidity constraints. If they move in period 1, household maximization yields period-1 housing demand $h_1^\ast = \min \{h_1^u, h_1^\ast\}$, and an optimal consumption choice $c_1^\ast$ with corresponding period-2 debt $Rk_2^\ast$.\footnote{Note that since households are forward-looking, their unconstrained housing choice is not, in general, given by $h_1^u = A_1 ((1 + \tau_1) p_1)^{\epsilon_1}$. In particular, the tax rate in period 2, $\tau_2$, may affect housing choices in period 1.}
and their period-2 debt is \( k_2 = k_1 - s_1 \).\(^{16}\) Households choose to move in period 1 whenever

\[
u_1 (c^*_1, h_1^*) + \delta V (h_1^*, Rk^*_2) \geq u_1 (y_1 - s_1, 1) + \delta V (1, R(k_1 - s_1)) .\]

As in period 2, condition (16) implicitly defines threshold levels for period-1 debt \( \bar{k}_1 \) and period-1 fixed costs \( \bar{q}_1 \) below which households move.

This dynamic model features four groups of households: Those who move in period 1, but not in period 2 (\( h_1 = h_1^* \) & \( h_2 = h_2 \)); those who move in both period 1 and period 2 (\( h_1 = h_1^* \) & \( h_2 = h_2^* \)); those who do not move in period 1, but move in period 2 (\( h_1 = 1 \) & \( h_2 = h_2^* \)); and those who never move (\( h_1 = 1 \) & \( h_2 = 1 \)). We denote the share of households who move in period \( t \) and are not downpayment constrained by \( U_t \), the share of households who move in period \( t \) but are downpayment constrained by \( C_t \), and the share of all movers in period \( t \) by \( M_t = U_t + C_t \). Then we can state the equilibrium conditions in each of the two periods as

\[
D_1 = U_1 E[h_1^* - 1|U_1] + C_1 E[h_1^* - 1|C_1] = 0, \tag{17}
\]

\[
D_2 = U_2 E[h_2^* - 1|U_2] + C_2 E[h_2^* - 1|C_2] = 0, \tag{18}
\]

where expectations are taken over household types \((A_1, A_2, \varepsilon_1, \varepsilon_2, \gamma_1, \gamma_2, k_1, q_1, q_2)\). These equilibrium conditions are directly analogous to the 1-period equilibrium condition (8).

Now let us consider a reduction of the transaction tax rate in period 1, keeping the transaction tax rate in period 2 unchanged. This should be interpreted as an unanticipated tax cut (as it happens in the first period of the model) and is known by taxpayers to be temporary, corresponding to the stimulus policy analyzed in our empirical application below. This tax stimulus has two conceptual effects on transaction levels in the housing market:

**Proposition 5 (Effects of Temporary Stimulus on Transaction Volumes).** A reduction of the period-1 transaction tax rate from \( \tau_1 \) to \( \tau_1 - d\tau_1 \), leaving the period-2 tax rate unchanged, causes

(i) a **timing effect** as a set of households who would have moved only in period 2 are induced to shift their house purchases forward to period 1;

(ii) extensive margin effects as a set of households who would have never moved are induced to move in period 1, and a set of households who would have moved only in period 2 are induced to move in both periods.

While the timing effect on transaction volume in period 1 is fully reversed in period 2, the extensive margin effects on transaction volume in period 1 are not reversed in period 2.

**Proof.** The proof is presented in appendix A. \(\square\)

This proposition implies that the extensive margin elasticities in period 1 with respect to \( 1 + \tau_1 \) are negative \((\eta_{k_1}^{\bar{k}_1}, \eta_{q_1}^{\bar{q}_1} < 0)\), while the extensive margin elasticities in period 2 with respect to \( 1 + \tau_1 \)

\(^{16}\)Note that here \( s_1 \) is an optimized savings choice, conditional on not moving in period 1, and reflects whether or not the household expects to be downpayment constrained in period 2.
are positive ($\eta_{t1}^c, \eta_{t2}^c > 0$). These elasticities include both the lasting extensive margin effect and the timing effect.

Besides these effects on the decision to move or not, changes in $\tau_1$ affect housing demand at the intensive margin in each period. There is an effect of $\tau_1$ on the housing demand by unconstrained movers in period 1 captured by the elasticity $\varepsilon_{t1}^u \equiv \frac{\partial h_t^u}{\partial \tau_1} 1+\tau_1 > 0$, and because households are forward looking, in general we have $\varepsilon_{t1}^u \neq \varepsilon$. By contrast, the housing demand of unconstrained households in period 2 is unaffected by the tax rate in period 1: $\varepsilon_{t2}^u = 0$. There is also an effect of $\tau_1$ on the housing demand by downpayment-constrained movers, and here there is both a direct effect on period-1 demand ($\varepsilon_{t1}^c \neq 0$) and an indirect effect on period-2 demand via changes in debt decisions in period 1 ($\varepsilon_{t2}^c \neq 0$). Turning to prices, similar reasoning implies that $\varepsilon_{t2}^u = 0$, while the other intensive margin elasticities with respect to $\tau_1$ are non-zero. The price in period 2 affects housing demand of all movers in period 2, $\varepsilon_{t2}^u, \varepsilon_{t2}^c \neq 0$. Forward-looking, unconstrained movers in period 1 also respond ($\varepsilon_{t1}^u \neq 0$), whereas constrained movers in period 1 are unable to respond ($\varepsilon_{t1}^c = 0$).

These intensive and extensive margin demand effects of a temporary tax change in period 1 lead to equilibrium price changes in both periods 1 and 2. We can characterize these dynamic tax incidence effects as follows:

**Proposition 6 (Effects of Temporary Stimulus on House Prices).** The elasticity of house prices in periods 1 and 2 with respect to the transaction tax rate in period 1 can be written as

$$
\left(\begin{array}{c}
\frac{dp_1}{d\tau_1} \\
\frac{dp_2}{d\tau_1} \\
\frac{dp_2}{d\tau_2} \\
\frac{dp_1}{d\tau_2}
\end{array}\right) = -D_p^{-1} \left(\begin{array}{c}
\frac{1}{p_1} \left(U_1 E [\varepsilon_{t1}^u h_1^u | U_1] + C_1 E [\varepsilon_{t1}^c h_1^c | C_1] + M_1 E [\eta_{t1}^c (h_1^c - 1) + \eta_{t1}^u (h_1^u - 1) | M_1]\right) \\
\frac{1}{p_2} \left(C_2 E [\varepsilon_{t2}^c h_2^c | C_2] + M_2 E [\eta_{t2}^c (h_2^c - 1) + \eta_{t2}^u (h_2^u - 1) | M_2]\right)
\end{array}\right)
$$

where

$$
D_p^{-1} = \left(\begin{array}{cc}
\frac{\partial D_1}{\partial p_1} & \frac{\partial D_1}{\partial p_2} \\
\frac{\partial D_2}{\partial p_1} & \frac{\partial D_2}{\partial p_2}
\end{array}\right)^{-1}
$$

is the inverse of the price gradient matrix of the excess demands, in which

$$
\frac{\partial D_1}{\partial p_1} = \frac{1}{p_1} \left(U_1 E [\varepsilon_{t1}^u h_1^u | U_1] + C_1 E [\varepsilon_{t1}^c h_1^c | C_1] + M_1 E [\eta_{t1}^c (h_1^c - 1) + \eta_{t1}^u (h_1^u - 1) | M_1]\right)
$$

$$
\frac{\partial D_1}{\partial p_2} = \frac{1}{p_2} \left(U_1 E [\varepsilon_{t2}^u h_2^u | U_1] + M_1 E [\eta_{t1}^c (h_1^c - 1) + \eta_{t1}^u (h_1^u - 1) | M_1]\right)
$$

$$
\frac{\partial D_2}{\partial p_1} = \frac{1}{p_1} \left(C_2 E [\varepsilon_{t2}^c h_2^c | C_2] + M_2 E [\eta_{t2}^c (h_2^c - 1) + \eta_{t2}^u (h_2^u - 1) | M_2]\right)
$$

$$
\frac{\partial D_2}{\partial p_2} = \frac{1}{p_2} \left(U_2 E [\varepsilon_{t2}^u h_2^u | U_2] + C_2 E [\varepsilon_{t2}^c h_2^c | C_2] + M_2 E [\eta_{t2}^c (h_2^c - 1) + \eta_{t2}^u (h_2^u - 1) | M_2]\right)
$$

and the intensive margin elasticities ($\varepsilon_{t1}^u, \varepsilon_{t1}^c, \varepsilon_{t2}^u, \varepsilon_{t2}^c$, for $t = 1, 2$) and extensive margin elasticities ($\eta_{t1}^c, \eta_{t1}^u, \eta_{t2}^c, \eta_{t2}^u$, for $t, s = 1, 2$) are defined analogously to the static model.
Proof. Applying the implicit function theorem to the system of equations \((D_1, D_2) = (0, 0)\) and following the same steps as the proof of proposition 3 yields the result.

Equation (19) is a natural extension of equation (9) to the 2-period model, and its fundamental intuitions carry over. For example, in the absence of downpayment constraints \(\gamma\), moving costs \(q\) and transaction taxes \(\tau\), all households costlessly reoptimize their housing choice in each period, and so \(C_1 = C_2 = 0\) and the extensive margin elasticities are all 0. In this case, we have \(\frac{dp_1/p_1}{d\tau_1/(1+\tau_1)} = -1\) and \(\frac{dp_2/p_2}{d\tau_1/(1+\tau_1)} = 0\). Introducing moving frictions through \(\gamma, q, \tau\) drives a wedge between households’ preferred houses and the houses they can afford, and places a floor on the net benefit households must receive from moving before they are willing to move. These forces mean that temporary transaction tax cuts can affect prices in both periods, and can have large and permanent effects on transaction volumes, as we shall see in our empirical application.

3 Context and Data

3.1 The UK Property Transaction Tax: Notches and Reforms

The UK property transaction tax—Stamp Duty Land Tax (SDLT)—is imposed on the transaction value of land and any construction on the land, known as the “chargeable consideration”\(^{17}\). This is defined in the broadest possible terms to include anything of economic value given in exchange for land or property, including money, goods, works or services, and transfers of debts. The statutory incidence of the SDLT falls on the buyer, who is required to file a stamp duty return and remit tax liability to HMRC within a few weeks of the completed transaction. The SDLT is a significant source of government revenue in the UK, much more so than other wealth transfer taxes such as inheritance taxation and capital gains taxation. The SDLT has raised revenue of around 0.6% of GDP over recent years\(^{18}\), and the political debate in the UK suggests that future rates (particularly on highly priced properties) are more likely to go up than down.

A central aspect of the stamp duty is that it features discrete jumps in tax liability—notches—at threshold property prices. Tax liability is calculated as a proportional tax rate times the transacted property price, with different tax rates in different price brackets. Hence, as the purchase price crosses a bracket threshold, a higher tax rate applies to the entire amount and not just the portion that falls above the threshold as in standard graduated schedules. Figure 2 illustrates the stamp duty schedule for residential property in tax year 2012–13\(^{19}\). The schedule features five notches as the proportional tax rate jumps from zero to 1% at a price of £125,000; from 1% to 3% at a price of £250,000; from 3% to 4% at a price of £500,000; from 4% to 5% at a price of £1,000,000; and finally

---

\(^{17}\)The chargeable consideration includes the buildings and structures on the land as well as fixtures and fittings (such as in bathrooms and kitchens), but excludes freestanding furniture, carpets or curtains. If such extras are included in the sale, the buyer and seller are to agree on the market value of these extras and subtract it from the chargeable consideration. See http://www.hmrc.gov.uk/sdlt/calculate/value.htm for details.

\(^{19}\)The UK tax year for personal taxes runs from April 6 in one year to April 5 the next year.
from 5% to 7% at a price of £2,000,000. The schedule is different for residential property in certain disadvantaged areas (where the first bracket threshold is at a higher price) as well as for non-residential property. It is important to note that the buyer cannot mortgage the SDLT liability, it must be financed from savings, and so we should expect the SDLT to have particularly large effects on downpayment constrained buyers (as shown by our conceptual framework). It should also be noted that stamp duty schedules are not indexed for inflation, which creates “bracket creep” as property price inflation pushes houses into higher stamp duty brackets.

Another important aspect of the stamp duty is that it has been subject to a great deal of policy experimentation over the years. As shown in Table 1, the main policy experiments during our data period have been (i) changes in the location of the lower notch and (ii) the introduction of new notches at £1,000,000 in April 2011 and at £2,000,000 in March 2012. It is worth describing the specific features of some of those policy changes as they will be important for the empirical analysis.

For the lower notch, the most salient change was the so-called stamp duty holiday between 3 September 2008 and 31 December 2009, which moved the first notch point from £125,000 to £175,000 and thereby eliminated stamp duty in a £50,000 range. The motivation for the program was to provide housing stimulus during the Great Recession. The following features of the stamp duty holiday are important for our analysis. First, the beginning of the holiday was unanticipated as it was announced suddenly by the then Chancellor Alistair Darling on the day before its introduction. Although there was some media speculation about the possibility of a stamp duty holiday in the month leading up to the announcement, the details and start date of such a holiday were unknown. Second, the end of this holiday was anticipated. The initial announcement was that the holiday would last for one year (until September 2009), but in April 2009 this was extended until the end of 2009 and the government committed to no further extensions (and indeed did not grant any extensions). The sudden announcement of the stamp duty holiday and the preannounced commitment to its end date allow us to compare the effects of expected and unexpected changes in tax policy. In particular, the pre-announced end date creates a time notch (a discrete jump in tax liability at a cutoff date) allowing us to analyze short-term timing effects. Finally, as the stamp duty holiday applied only to properties in a certain price range, we are able to study the stimulus effects of the policy and subsequent reversal (medium-term timing) using a difference-in-differences design.

For the top notches, the introduction of a higher stamp duty rate above £1,000,000 was pre-announced a full year in advance, while the higher stamp duty rate above £2,000,000 was confirmed just one day before it took effect. Hence, the introduction of the £1,000,000 price notch (but not the £2,000,000 price notch) also creates a time notch that can be used to study anticipatory

---

20 At the £2,000,000 notch, the stamp duty rate jumps to 15% if the residential dwelling is purchased by certain “non-natural persons” such as corporations and collective investment schemes.
21 Another stimulus program was implemented specifically for first-time buyers between 25 March 2010 and 24 March 2012. This program temporarily abolished the notch at £125,000, thereby eliminating stamp duty in the range between £125,000 and £250,000 for first-time buyers.
behavior.

The UK stamp duty appears to be characterized by relatively high compliance. According to HMRC estimates, the so-called tax gap—the difference between taxes owed and taxes paid on a timely basis—is 4–5% of true stamp duty tax liability. This is lower than the tax gap estimates for most other taxes in the UK. As described above, the tax base is defined in an very comprehensive manner meaning that the scope for shifting or re-classification of specific features of the property to avoid the tax is limited. The one exception is the exclusion from the tax base of freestanding “extras” such as furniture and curtains. If such extras are part of the sale, the buyer and seller are to agree on the market value of these extras and subtract it from the chargeable consideration, which creates an opportunity to evade stamp duty by overvaluing such items (while undervaluing the rest of the property by the same amount). Most stamp duty evasion is likely to occur through this channel, although the extent of this is limited by the fact that large amounts of tax exempt extras is an audit trigger. Whenever stamp duty evasion is not facilitated through these tax exempt extras, there must be monetary side payments between the buyer and the seller in order to cover the difference between reported and true house prices. Such side payments are associated with substantial risk and are therefore likely to be very rare.\footnote{Monetary side payments are very risky for two reasons. First, almost all property transactions in the UK are facilitated by licensed real estate agencies, implying that side payments require collusion between a buyer, a seller and a real estate agency (typically with multiple employees). Such evasion collusion involving many agents is difficult to sustain (Kleven et al. 2016). Second, the scope for monetary side payments is further reduced by the existence of a considerable lag between agreeing on a house price and completing the contract (this lag is 2-3 months on average in the UK). If the house price reported to tax authorities is lower than the true house price, the buyer must make a side payment to the seller. If the buyer makes the side payment at the time of agreeing on the house price, the seller would be able to renege before completing the contract and it would be difficult for the buyer to recoup the payment. If instead the buyer promises to make the payment at the time of completing the contract, the seller would take his property off the market with no credible commitment from the buyer that he would not renege later when the bargaining position of the seller may be weaker. Hence, such side payments would be associated with substantial risk for either the buyer or the seller or both.}

3.2 Data and Raw Time Series Evidence

The empirical analysis is based on administrative data covering the universe of stamp duty returns in the UK from November 2004 to October 2012. Since most property transactions require the filing of an SDLT return (the main filing exemption being for property transactions under £40,000), our data is close to the universe of property transactions in the UK. The full dataset contains about 10 million transactions. The dataset contains rich tax return information for each transaction, but has very little information outside the tax return.

The housing market has seen substantial turmoil during the period we consider. Figure 3
shows the monthly number of house transactions (Panel A) and the monthly average property price (Panel B) in all of the UK and in London alone. The figure shows nominal prices (real prices give the same qualitative picture) and normalizes both the price and the number of transactions to one at the start of the period. We make the following observations. First, housing market activity collapses between late 2007 and early 2009 as the number of transactions falls by around two-thirds. There has been some recent recovery, but activity is still far from pre-recession levels. Second, property prices also fall between late 2007 and early 2009, but the price drop is less dramatic and the subsequent recovery much stronger. Third, property prices (though not activity) in London have evolved differently than in the rest of the UK during the recession. While UK-wide property prices have recovered only partially in the past couple of years, London property prices are almost back on their pre-recession trend. Fourth, the recovery in house prices and activity throughout 2009 coincides with the stamp duty holiday, which has been used as an argument that the policy had the desired effect. We will take a quasi-experimental approach to evaluate how much of the recovery (if any) can indeed be explained by the stamp duty holiday. Finally, average house prices in London feature a sharp spike in early 2011 and a subsequent dip, which constitutes our first piece of evidence of a behavioral response to stamp duty incentives. This spike reflects excess trading of houses above £1,000,000 just before the pre-announced introduction of the £1,000K stamp duty notch on 6 April 2011 and the dip reflects missing trading of such houses just after the introduction of the notch—a short-term timing response to an anticipated tax change.

4 House Price Responses to Transaction Taxes: Price Notches

4.1 Static Price Notches

This section presents static results using price notches during periods when they are stable. We consider residential property transactions that incur a stamp duty land tax liability. Figure 4 considers the two notches located at cutoff prices of £250,000 (Panel A) and £500,000 (Panel B), both of which have remained in place throughout the period of our data. Each panel shows the empirical distribution of house values (blue dots) as a histogram in £5,000 bins and an estimated counterfactual distribution (red line). Following Chetty et al. (2011) and Kleven & Waseem (2013), the counterfactual distribution is estimated by fitting a flexible polynomial to the empirical distribution, excluding data in a range around the notch, and allowing for round-number fixed effects to capture rounding in the price data. The excluded range is demarcated by vertical dashed lines;
the lower bound is set at the point where excess bunching starts and the upper bound is set at the point where the hole ends (where the empirical distribution above the cutoff changes slope from positive to negative).

Before reporting our results, it is worth qualifying the estimated “counterfactual distribution” and what it is supposed to achieve in this context. Two points are worth noting. First, because the estimation uses data above the notch that may be affected by extensive responses, the procedure does not yield the full counterfactual distribution that would prevail if the notch were eliminated. As discussed by Kleven & Waseem (2013), the estimation procedure intends to provide a “partial counterfactual” stripped of intensive responses, but not extensive responses. We may think of the partial counterfactual as the border of the light-gray area in Panel D of Figure 1. Second, even this partial counterfactual distribution may be difficult to estimate precisely in the range above the notch, especially in situations where the hole is large and diffuse (Kleven & Waseem 2013; Kopczuk & Munroe 2015). The estimation of missing mass above the notch may be quite sensitive to parametric assumptions such as the order of the polynomial and the width of the excluded range. For this reason, none of our key results in this paper will rely on being able to estimate the counterfactual distribution and missing mass above the notch. The estimation of house price responses in this section as well as the estimation of extensive and timing responses in the next section make use only of our bunching estimates. And these bunching estimates are extremely robust due to the fact that observed bunching is very sharp and that the empirical distribution is very flat and smooth below the bunch. Our results are essentially unaffected by the degree of the polynomial, the excluded region, the binwidth, and whether we estimate bunching using only data below the notch. Hence, while we show estimates of the counterfactual distribution and missing mass in the following figures (as they may be of independent interest), it is important to keep in mind that these estimates are not strictly necessary for what we do.

In Figure 4, each panel shows estimates of excess bunching below the notch scaled by the counterfactual frequency at the notch \( b \), the size of the hole (missing mass) above the notch scaled by the counterfactual frequency at the notch \( m \), the difference between these two \( m - b \), the average multiples of the round numbers in the set \( \mathcal{R} \), where \( \mathcal{R} = \{500, 1000, 5000, 10000, 25000, 50000\} \), \( \mathbb{N} \) is the set of natural numbers, and \( I \{\cdot\} \) is an indicator function. Finally, the third term in (20) excludes a region \((v^-, v^+)\) around the notch that is distorted by bunching responses to the notch, and \( \mu_i \) is a residual reflecting misspecification of the density equation. Our estimate of the counterfactual distribution is defined as the predicted bin counts \( \hat{c}_i \) from (20) omitting the contribution of the dummies in the excluded range, and excess bunching is estimated as the difference between the observed and counterfactual bin counts in the part of the excluded range that falls below the notch \( \hat{B} = \sum_{i=v^-}^{v^+} (c_i - \hat{c}_i) \).

We may also define an estimate of missing mass (the hole) above the notch as \( \hat{M} = \sum_{i=v^+}^{\bar{v}} (\hat{c}_i - c_i) \), but this statistic is not used in the estimation of house price responses and house price elasticities (see section 2.1). Standard errors on all estimates are calculated based on a bootstrap procedure as in Chetty et al. (2011). As a robustness check we have tried values between 4 and 7 for the order of the polynomial and our results are not significantly altered.

To simplify, our estimation of the counterfactual distribution ignores the marginal shift in the distribution above the hole due to intensive responses in the interior of the upper bracket. It is feasible to account for this shift in the distribution when estimating the counterfactual by using an initial estimate of the house price elasticity (based on ignoring the shift in the upper distribution) to obtain an initial estimate of the distribution shift, re-estimating the counterfactual and the house price elasticity to respect the initial estimate of the distribution shift, and continuing the procedure until the estimation converges. However, given the size of the incentive (a marginal tax rate change of 1–2% above the notch) and the house price elasticities that we find, this shift will be extremely small and have no substantive effect on any of our conclusions.
house price response to the notch \( (\Delta \bar{v}) \), and the tax liability change at the notch \( (\Delta \text{Tax}) \). Our main findings are the following. First, both notches create large and sharp bunching below the cutoff. Excess bunching is 1.85 and 1.64 times the height of the counterfactual distribution at £250,000 and £500,000, respectively, and is strongly significant in each case. Second, both notches are associated with a large hole in the distribution above the cutoff. The size of the hole is larger than the size of excess bunching, although the difference between the two is not statistically significant from zero. Third, the hole in the distribution spans a £25,000 range above each cutoff, implying that the most responsive agents reduce their transacted house value by five times as much as the jump in tax liability of £5,000. Fourth, the average house price response is £10,000 at both the £250,000 notch and the £500,000 notch, a response that is twice as large as the tax jump.

Interpreting the third and fourth results in the context of our model with downpayment constraints in section 2, a response of £25,000 is consistent with the most responsive households being downpayment constrained and having a loan-to-value ratio of 80%. In the UK, many households have an LTV of 80% as this level is associated with a large notch in mortgage interest rates. Similarly the average price response suggests an average LTV ratio amongst bunchers of 50%, consistent with a mixture of downpayment constrained, highly leveraged buyers, and unconstrained buyers.

We now turn to the lower notch, the location of which has changed several times during the period under consideration. The cutoff was located at £60,000 until 16 March 2005, at £120,000 between 17 March 2005 and 22 March 2006, at £125,000 between 23 March 2006 and 2 September 2008, at £175,000 between 3 September 2008 and 31 December 2009, and again at £125,000 from 1 January 2010 onwards. This section takes a static approach by considering bunching responses within each of these five periods separately, while the next section investigates dynamic adjustment paths around the reform episodes. Figure 5 shows results for the five periods in separate panels, each of which is constructed as in the Figure 4. The findings for the lower notch are qualitatively consistent with those for the other notches, with a clear and statistically significant bunching response to the tax notch in each period. The size of the bunch and the hole is smaller at the lower notch than at the upper notches, but so is the size of the notch. The effect of the notch on the average transacted house value is between £3,500 and £5,000, or about 4–5 times the size of the tax liability jump, implying that responses are proportionally larger at the bottom.

Moreover, based on visual inspection of the hole (which is not as sharp here as for the upper notches), the most responsive households reduce their transacted house value by as much as 20 times the size of the notch. These extremely large responses are consistent with the most responsive households being downpayment constrained at an LTV ratio of 95%, not uncommon among first-time buyers in our sample period. These findings are consistent with the observation that a greater share

\[ 26 \text{As we show in appendix B.1 this house value response can be used to place an upper bound on the structural elasticity } \varepsilon \text{ in our theoretical framework in section 2. Implementing this yields upper bounds of } \varepsilon_{250} = 0.05 (0.025) \text{ at } £250,000 \text{ and } \varepsilon_{500} = 0.03 (0.024) \text{ at } £500,000. \]

\[ 27 \text{As we show in appendix B.1 this house value response implies an upper bound on the structural elasticity } \varepsilon. \text{ Implementing this yields upper bounds on } \varepsilon \text{ of 0.17 (0.097) in panel A; 0.09 (0.038) in panel B; 0.09 (0.052) in panel C; 0.05 (0.051) in panel D; and 0.09 (0.027) in panel E.}\]

\[ 28 \text{For example, in 2006, 13\% of mortgage originations were at LTV ratios above 90\% (Financial Conduct Authority.} \]
of properties at the lower end of the price distribution are starter homes being bought by highly leveraged first-time buyers.

In 2011 and 2012, the government introduced two new notches affecting very high value properties, one at £1 million on 6 April 2011 and another one at £2 million on 22 March 2012. The stamp duty notch at £2 million is commonly referred to as the “mansion tax”. Even though these notches were introduced close to the end of our data period, we see very clear house price distortions in the data as shown in Appendix Figure B.1. This figure is constructed in the same way as the previous ones, except that the counterfactual distribution is obtained differently. We take advantage of the tax reform (notch introduction) by comparing the empirical house price distribution after the introduction of the notch to the empirical distribution in the year leading up to the introduction of the notch. The results are qualitatively very similar to the previous results, with an average house price response of £30,000 at the £1 million notch (3 times the tax liability jump of £10,000) and £100,000 at the £2 million notch (2.5 times the tax liability jump of £40,000).

4.2 Moving Price Notches

This section investigates the dynamics of behavioral adjustment to the changes in the position of the lower notch introduced by the stamp duty holiday. This stimulus policy moved the notch from £125,000 to £175,000 on 3 September 2008, and then moved it back from £175,000 to £125,000 on 1 January 2010. Recall that the start of the holiday was unanticipated while the end of the holiday was anticipated. When interpreting the findings, it is useful to keep in mind that there is a lag between agreeing on a purchase price and completing the housing contract. In the UK housing market, this lag is under 90 days for most transactions and about 60 days on average (Besley et al. 2014). Since the official transaction date in our data refers to contract completion, the time it takes for the market to settle into a new equilibrium after an unanticipated tax change is bounded from below by about 3 months.

To analyze dynamics we estimate bunching separately for each month between January 2007 and August 2011 at both £125,000 and £175,000. Figure 6 summarizes the results by showing the monthly bunching estimate \( b \) at the £125,000 threshold (blue dots) and the £175,000 threshold (orange crosses) with 95% confidence intervals around each series. The solid vertical lines in Figure 6 demarcate the implementation dates of the reforms, while the dashed vertical line demarcates the de facto time at which the first, unanticipated reform took full effect given the lag between agreed and completed house purchases. The individual monthly bunching figures underlying the estimates \( b \) in Figure 6 are presented in the Appendix Figures B.2 and B.3.

The following main findings emerge from the figure. First, at the beginning of the holiday it

---

29 Animated versions of the monthly bunching figures that show the dynamics vividly can be found on our websites, for example at http://www.henrikkleven.com/uploads/3/7/3/1/37310663/best-kleven_landnotches_april2013_videos.pdf
takes 3–4 months for bunching at £125,000 to disappear, and about 3 months for bunching at the new £175,000 threshold to build up to a steady state. These response times correspond roughly to the lower bound for unanticipated tax changes created by the contract completion lag described above. Second, steady-state bunching at £175,000 \( (b \approx 0.9) \) is larger than at £125,000 \( (b \approx 0.6) \), consistent with the former being a larger notch. Third, at the pre-announced end of the holiday, response times are even faster: bunching at £175,000 disappears almost immediately and the re-emergence of bunching at £125,000 happens within about 2 months. The immediate disappearance of bunching at £175,000 shows that buyers and sellers did indeed anticipate the end of the holiday and made sure to complete their housing contracts before the end of December 2009. The next section investigates such short-term timing behavior in greater detail.

The figure highlights just how sharply house prices react to tax notches and to changes in tax notches even at the monthly level. Once we account for the built-in sluggishness due to the time it takes to complete a housing contract, the market adjusts to a new stable equilibrium remarkably quickly. Compared to recent bunching evidence from labor markets (e.g. Saez 2010; Chetty et al. 2011; Kleven & Waseem 2013; Gelber et al. 2015), the remarkable sharpness of our evidence suggests that behavioral responses in the housing market are much less affected by optimization frictions such as inattention, inertia, etc. Our evidence suggests that agents in the housing market respond precisely and quickly to tax incentives.

5 Timing and Extensive Responses to Transaction Taxes: Stimulus

We saw in the previous section that house prices respond sharply and quickly to transaction taxes. In this section, we investigate the effect of the transaction tax on whether individuals transact, and if so, when they choose to transact, again studying the impact of the stamp duty holiday that temporarily eliminated the stamp duty on house purchases in the £125,000–£175,000 price range. The stamp duty holiday was an unanticipated stimulus program with a fixed and fully anticipated end date. Conceptually, as discussed in section 2.4, we expect such a policy to have two effects on transaction volumes. First, there will be a timing effect as some agents who would have transacted a house in the future bring that transaction forward to the current period. Second, there will be extensive margin effects as some agents engage in additional house transactions over their lifetime.

To evaluate fiscal stimulus programs of this kind, it is crucial to obtain estimates not just of the total stimulus effect during the program (timing and extensive margin effects), but also of the degree to which it is driven by timing (all of which will be reversed after program withdrawal) and the length of the horizon over which there is re-timing (which determines the speed of reversal). This section provides compelling evidence on all three questions. We also combine our stimulus estimates with survey data on moving-related household spending in order to provide a lower bound on the effects on real economic activity (not including general equilibrium effects of increased homeowner mobility, Keynesian multiplier effects, etc.).

We begin the analysis by studying short-term timing responses around the anticipated end
date of the stamp duty holiday, and then turn to the analysis of medium-term timing and extensive margin responses.

5.1 Short-Term Timing Responses to Anticipated Tax Changes

As described in section 3.1, the tax increase at the end of the stamp duty holiday was fully anticipated, creating a *time notch* on 1 January 2010 for houses between £125,000 and £175,000. This time notch creates a strong incentive for individuals to conclude their transactions before New Year, and bunching in the timing of transactions allows us to estimate this short-term timing response.

Before discussing the empirical results, we make two remarks. First, the housing market almost shuts down between Christmas and New Year, so the notch is effectively a notch just before Christmas. Hence, agents should respond to the notch by moving the date of purchase from the early weeks of 2010 to the third week of December 2009. Second, the existence of the Christmas holiday (with or without a tax notch) may in itself lead to a piling up of house transactions in the third week of December. This means that we cannot analyze the time notch using a “pure” bunching strategy as observed bunching in transactions before Christmas 2009 may overstate the response to the tax notch. We therefore pursue a difference-in-bunching strategy by comparing bunching in the treated group (transactions between £125,000–£175,000 in December 2009) to bunching in control groups (other years and/or other price ranges).

Figure 7 shows the weekly number of transactions around New Year in different price ranges and different years. Panel A compares the treated price range £125,000–£175,000 in the treated period 2009/10 to surrounding price ranges in the same period. The treated group features very strong bunching just before the notch and a large hole after the notch. The control groups also feature bunching and a hole (Christmas effect), but to a much smaller extent. Furthermore, the shutdown of activity between Christmas and New Year is less extreme in the treated group than in the control groups. To evaluate the timing response, we estimate excess bunching in each distribution during the last three weeks of the year using a bunching approach analogous to our approach for the price notches.\(^\text{30}\) The timing response is then given by the difference between bunching in the treated range and average bunching in the surrounding control ranges (D-i-Bunching in the figure). We find that excess mass induced by the time notch is almost 3 times the height of the counterfactual and strongly significant, implying that the average timing response to the notch is 3 weeks.

Panel B is constructed in the same way, except that it compares the treated price range £125,000–£175,000 in the treated period 2009/10 to the same price range in other periods (one year earlier or

\(^{30}\)To quantify bunching, we estimate a counterfactual number of weekly transactions based on the following regression

\[
c_w = \sum_{j=0}^{7} \beta_j (z_w)^j + \eta I \{w \in \text{end of month}\} + \sum_{k=w^-}^{w^+} \gamma_k I \{w = k\} + \mu_w, \tag{21}
\]

where \(c_w\) is the number of transactions in week \(w\) and \(z_w\) is the distance of week \(w\) from the end of 2009. The second term is a fixed effect for weeks at the end of the month (which feature heavier trading in every month), while the third term excludes weeks in a range \((w^-, w^+)\), which we set to include the last 3 weeks of 2009 and the first 10 weeks of 2010.
two years earlier). The results are very similar, with estimated excess mass before the notch being somewhat larger and still strongly significant. The placebo tests in the bottom panels repeat the strategy in Panel A (comparing different price ranges), but one year or two years earlier. In each case, the timing effect is close to zero and statistically insignificant.

Overall, this provides very compelling evidence of short-term timing responses to anticipated tax changes, consistent with the sharpness of price responses discussed above. These findings contribute to the previous literature on the timing of the realization of taxable income (Auerbach 1988; Burman & Randolph 1994; Goolsbee 2000) and medical expenditures (Einav et al. 2015).

5.2 Medium-Term Timing and Extensive Margin Responses to Stimulus

The stamp duty holiday temporarily eliminated the transaction tax in the price range £125,000–£175,000 without changing the tax in neighboring price ranges, presenting us with an opportunity to pursue a difference-in-differences approach to estimate medium-term timing and extensive margin responses to the stimulus. A naïve first cut at this (that we refine shortly) is to compare the transaction volumes over time in the treated range £125,000–£175,000 and in a nearby control range. This is done in Figure 8, which shows the log number of transactions in the treated range £125,000–£175,000 (blue dots) and a control range defined as £175,000–£225,000 (orange crosses) in each month from September 2006 to October 2012. We have normalized the log number of transactions in each series by subtracting the average log number of transactions in the pre-treatment period (the 2 years leading up to the holiday) in order to make visual comparison of the two series easier. The solid vertical lines mark the beginning (3 September 2008) and the end (31 December 2009) of the stamp duty holiday.

The two series display completely parallel trends leading up to the holiday and then begin to diverge precisely when the holiday starts. The positive effect of housing stimulus in the treated range increases during the first months of the holiday and features a sharp spike in the last month as people rushed to take advantage of the stimulus before it expired. After the holiday, there is a sharp dip in the treated series during the first month, but only slight additional reversal thereafter as the treated group is marginally below the control group for about a year and then converges with the control group in the later part of the sample. Taken at face value, this graph implies that housing stimulus gave a large boost to housing market activity during the policy with very weak reversal after the policy (apart from the short-term timing effect shown by the spike and dip right

---

31 As described in section 3.1, a stamp duty relief scheme was implemented for first-time buyers in the price range £125K–£250K between 25 March 2010 and 24 March 2012 (after the end of the stamp duty holiday). Since we are also interested in estimating reversal after the stamp duty holiday, it is important to make sure that the first-time buyers’ relief scheme is not a confounding factor during the reversal period. This motivates using a control range (£175K–£225K) just above the treatment range (£125K–£175K), ensuring that both groups fall within the range eligible for first-time buyers’ relief and therefore face the same incentive from this scheme. There could still be a concern that the treatment and control range respond differently to the first-time buyer incentive, which would be a confounding factor in the reversal estimates. To alleviate this concern, we drop all transactions claiming first-time buyers’ relief throughout the analysis in this section. Including those observations only strengthens our findings below of incomplete reversal after the end of the stamp duty holiday.
around the stimulus end date analyzed in section 5.1 above). However, we argue that this both overstates the positive impact of the stimulus policy and understates the slump after the end of the policy.

The issue with interpreting the evidence in Figure 8 is that treatment assignment (whether a transaction takes place in the £125,000–£175,000 price range) is endogenous to movements across bracket cutoffs. The stamp duty holiday creates an incentive to move into the treated price bracket from both sides. At the upper end of the range, the holiday creates a new notch at £175,000 that induces agents to move from a region above the cutoff to a point just below the cutoff (bunching). We have seen in section 4 that bunching responses at £175,000 do indeed occur, and this increases activity in the treated range compared to the control range. At the lower end, the holiday eliminates the notch at £125,000 and therefore induces bunchers at this cutoff to move back into the hole above the cutoff. We have seen that the disappearance of bunching at £125,000 also occurs, and this further increases activity in the treated range compared to the control range. Hence, the positive effect of housing stimulus in Figure 8 combines the true effect on overall activity levels with endogenous price responses resulting from the change in the location of the notch.

We consider two ways of dealing with this endogeneity issue. The first and simplest way is to widen the treatment range on each side (below £125,000 and above £175,000) in order to ensure that any price manipulation around notches occurs within the treatment range and so does not affect measured activity levels in this range. By including transactions outside the tax holiday area in the treatment group, this strategy captures an intent-to-treat effect and therefore understates the impact on the actually treated. We consider this intent-to-treat strategy in Figure 9 in which we expand the treatment range to £115,000–£195,000 and compare with the range £195,000–£235,000. Based on the bunching evidence presented earlier, this expanded treatment range fully encompasses the bunching interval below £125,000 and the hole interval above £175,000.

Figure 9 presents our findings in four panels. Panel A shows the normalized log number of transactions in each month in the treatment and control ranges (exactly as in Figure 8), while Panel B shows the differences in these log counts in each month. Panel B highlights the stimulus effects in a more striking way by differencing out the seasonal and cyclical aspects of the two time series. These two panels show that the intent-to-treat strategy produces stimulus effects that are qualitatively similar to those in the previous figure, but that the boost in activity during the holiday is smaller and the lull in activity after the holiday is larger. Panel B shows that the lull in activity lasts for approximately 12 months, after which the two series are parallel again. In order to illustrate the total extent of reversal after the holiday, Panel C depicts the cumulated sums of the flows from both Panel A (levels) and Panel B (differences). This graph shows clearly that reversal is far from complete: the cumulated differences fall by less than half of their initial rise during the 2\( \frac{1}{2} \) year post-stimulus period in the figure.

To put numbers on these effects, we run the following difference-in-differences regression on a

---

\[ \text{Note that the control group also features a (much smaller) spike and dip around the end of the stamp duty holiday driven by the Christmas/New Year effect as discussed in section 5.1 above.} \]
panel of monthly activity levels in price bins of £5,000:

\[ n_{it} = \alpha_0 Pre_t + \alpha_H Hol_t + \alpha_R Rev_t + \alpha_P Post_t + \alpha_T Treated_t + \beta_H Hol_t \times Treated_t + \beta_R Rev_t \times Treated_t + \beta_P Post_t \times Treated_t + \nu_{it}, \]  

(22)

where \( n_{it} \) is the log number of transactions in price bin \( i \) and month \( t \), \( Pre_t \) is a dummy for the pre-period September 2006–August 2008, \( Hol_t \) is a dummy for the stamp duty holiday period September 2008–December 2009, \( Rev_t \) is a dummy for the post-holiday reversal period January–December 2010, \( Post_t \) is a dummy for the later months January 2011–October 2012, \( Treated_t \) is a dummy for the treated price range £115,000–£195,000, and finally \( \nu_{it} \) is an error term that we cluster by price bin to account for serial correlation (Bertrand et al. 2004). The coefficients we are interested in are \( \beta_H \) (positive effect during stimulus) and \( \beta_R \) (negative effect after stimulus due to re-timing).

Panel A of Figure 9 shows our estimates of the coefficients \( \beta_H \), \( \beta_R \) and \( \beta_P \). The coefficient \( \hat{\beta}_H = 0.17 (0.083) \) implies that average monthly activity was approximately 17% higher during the holiday than it would have been in the absence of stimulus. The coefficient \( \hat{\beta}_R = -0.10 (0.021) \) implies that average monthly activity was about 10% lower in the first year after the stimulus than it otherwise would have been. Together, these estimates imply that \(- (12 \hat{\beta}_R) / (16 \hat{\beta}_H) \) = 42% of the additional activity created by the stimulus program was a timing response by people bringing forward their purchases in order to benefit from the tax cut, while the remaining 58% was a lasting extensive margin effect. These large and lasting effects are consistent with our theoretical framework in section 2 in which even small changes in the transaction tax are leveraged up into large changes in the house that downpayment constrained households can afford, and hence can have large impacts on their decision to participate in the housing market.

As the end date of the reversal period (December 2010) was chosen visually, there might be a concern that our estimate of total reversal is sensitive to the chosen end date. In order to address this, Panel D of Figure 9 shows total reversal estimates for all possible end dates, with the vertical line corresponding to the baseline assumption of 12-months reversal.\(^{33}\) The graph shows that the reversal estimate is below 60% in all specifications and hence the finding of incomplete reversal is robust.

We now turn to the second and more sophisticated way of dealing with endogenous movements across notches. This strategy exploits the fact that we have monthly bunching estimates of price responses to notches and can therefore directly control for them. That is, we may consider the number of transactions in different price brackets adjusted for the effect of bunching behavior in each month. To be precise, in every month, the estimated bunching mass just below £125,000 is reallocated to the treatment range £125,000–£175,000 while the estimated bunching mass just below £175,000 is reallocated to the control range £175,000–£225,000. By using these bunching-adjusted counts in our difference-in-differences strategy, we avoid bias from selection into treatment.

\(^{33}\)The point estimates are obtained by performing the regression (22) using different reversal period cutoffs and calculating \(- \left( \sum_t Rev_t \times \hat{\beta}_R \right) / (16 \hat{\beta}_H), \) where \( \sum_t Rev_t \) denotes the length of the reversal period in the particular regression.
The results of this bunching-adjusted strategy are presented in Figure 10, which is constructed exactly as the previous figure. We see that the effects are qualitatively similar, but slightly stronger than those from the intent-to-treat strategy: The holiday boost is about 20% (as opposed to 17% before) and the reversal is about 8% for 12 months (as opposed to 10% before).34 These effects reduce our estimate of total reversal as a share of total stimulus, and the estimate is even more robust to the chosen end date, never rising above 40%.35

To be clear, the strength of our difference-in-differences evidence lies in the following features of the data: the completely parallel trends of the treatment and control groups before and after the stimulus policy, along the sharp changes occurring in the exact months that the policy is first introduced and subsequently withdrawn. It is very unusual for difference-in-differences studies to have such double verification of parallel trends before and after, along with sharp treatment effects at the monthly (rather than annual) level. For our estimates to be driven by confounding shocks, there would have to be both positive and negative shocks that affect neighboring price bands differently and according to a very specific monthly pattern.

To eliminate any lingering concerns about confounders, Figure 11 shows a series of placebo estimates of the holiday effect $\beta_H$. These estimates are based on a difference-in-differences regression like (22), but instead of having only two groups (treated and untreated) in a relatively narrow price range, we allow for each 10K price bin to have its own holiday effect and consider a wider price range. To be precise, we estimate the holiday effect $\beta_H$ for each 10K bin between £115,000–£375,000 using the range £375,000–£425,000 as the comparison group. If the underlying trends were non-parallel across the house price distribution, this would result in non-zero estimates of $\beta_H$ even as move up through the untreated part of the distribution (i.e., above £195,000 when accounting for bunching responses just above the treated range). The graph lends strong support to our identification strategy: the series of placebo estimates are consistently close to zero and are almost always statistically insignificant.

In addition to providing placebo tests, Figure 11 sheds light on the potential for spillovers between the treated price range and neighboring price ranges. Spillovers between treatments and controls may arise from the presence of real estate chains, i.e. linked house transactions whereby households buying new houses are simultaneously selling their existing houses (exactly as mod-

---

34Since these estimates require us to run the difference-in-differences regression (22) using bunching-adjusted activity levels in £5K bins, we have to reallocate bunching mass below the two cutoffs to specific £5K bins above the cutoffs. We reallocate bunching mass below a cutoff to the five bins above the cutoff in proportion to the amount of missing mass (difference between the estimated counterfactual mass and the observed mass) in each bin. Furthermore, since activity levels are adjusted using estimated bunching at the thresholds, we are introducing measurement error to our dependent variable coming from potential misspecification of the counterfactual when calculating the amount of bunching at £125K and £175K. However, since this measurement error is effectively noise in the dependent variable, it does not cause bias in our estimates, but simply increases our standard errors.

35The difference-in-differences estimates of the boost effect ($\hat{\beta}_H = 0.20$) and reversal effect ($\hat{\beta}_R = 0.08$) can be combined to yield estimates of the extensive margin elasticity in the short run (boost effect) and long run (boost effect net of reversal). The short-run extensive margin elasticity equals $\hat{\eta} = \frac{\hat{\beta}_H}{\Delta T/(1+T)} = 20.62 \ (2.18)$, while the long-run extensive margin elasticity equals $\hat{\eta} = \frac{\hat{\beta}_H + (12/16)\hat{\beta}_R}{\Delta T/(1+T)} = 14.3 \ (3.26)$. An earlier draft (Best & Kleven 2014) provides a simple welfare analysis of transaction taxes using these extensive margin elasticities.
elled in section 2). Such chains introduce the possibility that the stimulus-induced transactions in the treatment range trigger additional transactions outside that range. Such spillovers would make us underestimate the total effect of the tax holiday. However, Figure 11 suggests that chain spillovers outside the holiday region are not significant: because chain spillovers should be larger close to the treated region than farther away, they would create a declining series of placebo estimates above the treated range. The fact that we do not see such a declining pattern suggests that the stimulus effects are local to the directly treated range. It should be noted, however, that we cannot rule out chain effects in the immediately surrounding bins in which bunching responses depress transaction volumes during the holiday and thus hides potential spillovers. The possibility of such effects provides an argument for choosing the intent-to-treat strategy over the bunching-adjusted strategy, because the former would include any spillovers.36

Our stimulus findings stand in sharp contrast to Mian & Sufi (2012), who find complete and swift reversal following a short (1 month) stimulus program offering car transaction subsidies in the US. Apart from the fact that the housing market may work differently than the car market (for example with respect to downpayments and leverage), the contrast between our findings and those of Mian & Sufi (2012) suggests that stimulus policies that are of extremely short duration do not give households sufficient time to respond along the extensive margin and therefore have only short-term timing effects. Hence, our findings highlight the importance of the length of the stimulus program.37 Of course, while the strength of reversal is important for evaluating stimulus, it does not by itself indict or validate such policies as their key rationale is to create more economic activity when the economy is slack (even if this comes at the expense of less economic activity when the economy is tight). The next section provides a rough estimation of the immediate increase in real economic activity created by the UK housing stimulus program.

5.3 Spending Effects of Stimulus

While we have established that the stamp duty holiday had a large effect on transaction volume in the housing market (and therefore on household mobility), part of the motivation for the policy was also to stimulate household spending through the potential complementarities between mov-

36Note that, while the log effect $\beta_H$ is smaller under the intent-to-treat strategy, the baseline number of transactions is larger due to the wider treatment range. Hence the stimulus effect in terms of additional transactions created is actually somewhat larger under the intent-to-treat strategy than under the bunching-adjusted strategy, consistent with moderate local spillovers.

37Consistent with this, Appendix Figure B.4 uses the same strategy to analyze a permanent reform early on in our data period. On 16 March 2005, the bottom notch was permanently moved from £60,000 to £120,000. The reform cut the tax from 1% to 0% over the price range £60,000 to £120,000 while leaving the tax unchanged in neighbouring price ranges, allowing us to use our bunching-adjusted difference in differences strategy. Panel A shows the normalized log counts of monthly transaction volumes in the treatment range £60,000–£120,000 (blue circles) and the control range £120,000–£180,000 (orange crosses) together with the estimated treatment effect from a regression analogous to equation (22), while panel B shows the cumulative sums of the normalized log counts in the treatment and control ranges. The estimated coefficient $\hat{\beta}_P = 0.23 (0.018)$ implies that this permanent reform increased monthly transaction volumes by approximately 23% on average. This extensive response is even larger than the extensive response to the stamp duty holiday, consistent with the idea that these effects are increasing in the length of the time horizon of the policy as discussed in section 5.2. It is also worth noting that this reform was implemented during the height of the housing market boom, in sharp contrast to the stamp duty holiday implemented at the bottom of the recession.
ing house and spending. In particular, moving house is associated with substantial spending on items such as repairs and improvements, removals, furniture, appliances, and commissions. Investigating the spending effect of the UK housing stimulus program also allows for a comparison between our findings and previous work on the spending effect of fiscal stimulus such as income tax rebates (e.g. Shapiro & Slemrod 2003a,b; Johnson et al. 2006; Agarwal et al. 2007).

To estimate the effect of housing stimulus on moving-related spending, we use the UK Living Costs and Food Survey (LCFS). This dataset includes detailed consumption information and is a repeated cross-section covering 2001–2013.\(^{38}\) While in principle one could directly estimate the effect of the stamp duty holiday on spending in a difference-in-differences design, in practice such a strategy is not feasible due to limitations of the survey data such as small sample size, annual rather than monthly information, and unobserved house prices. We therefore adopt an alternative strategy that combines our difference-in-differences estimate of the effect on residential transaction volume (moving) with an “event-study” estimate of the effect of moving on spending using the survey data. This strategy exploits the power and precision of the administrative data as far as it goes, and then leverages the survey data only to estimate the last step from moving to spending.

As a first descriptive exercise, Table 2 compares spending in moving-related categories in the year of moving (year 0), in the year after moving (year 1), and in subsequent years (year 2+). Columns (1)–(3) show the level of spending in these different years, while columns (4)–(6) show the additional spending in year 0 and 1 (as compared to year 2+). Panel A of the table shows that households spend more on all categories in the year of moving, and that they continue to spend more on repairs and improvements (and only slightly more on other categories) in the year after moving. These numbers are consistent with the idea that households incur substantial moving-related expenditures in the year that they move, and that renovations extend into the following year. The total amount of additional spending in years 0 and 1 equals £6,428. Panel B converts average spending into percentages of the average house price (£230,000), adds commissions to estate agents (an average of 1.98%) and other service providers such as solicitors (an average of 1.24%), thus arriving at an initial estimate of the impact of moving on spending.\(^{39}\) We find that moving is associated with extra spending of about 5% of the house value in the first year and an additional 1% in the next year.

There are two main issues with interpreting these numbers that we now address. One issue is that moving-related spending may be cyclical, and in particular that movers spend less during recession periods such as the one we study. To investigate this, Figure 12 summarizes the results of performing the calculation in Table 2 separately for each year. The series in grey triangles show movers’ additional spending across all categories in year 0 (as in column 4 of the table), while the series in black dots show movers’ additional spending across all categories in year 0 and 1.

\(^{38}\)We exclude the 2008 survey round, because in this year the housing tenure variable (which we use in the empirical strategy described below) is corrupted.

\(^{39}\)A 2011 survey by Which? Magazine estimates that estate agents’ fees average 1.8% of the house price before VAT, or 1.98% with VAT (see http://www.which.co.uk/news/2011/03/estate-agents-fees-exposed-248666/). ReallyMoving (2012) estimates that other commissions and fees total £1,880 on average, and do not vary much with house value, so we scale this by the average value of houses bought in the range affected by the policy (£152,000).
combined (as in column 6 of the table). We see that moving-related spending is indeed cyclical, with more spending when housing market activity is high (2003–2006 and 2013) than when housing market activity is low (2001–03 and 2007–2012). In light of this, in what follows we present estimates separately for low-activity years and for all years pooled.

Another issue is that moving may be endogenous to factors that impact directly on spending such as income shocks or childbirth. We can alleviate such concerns in two ways: by controlling for a number of observables in our survey, and by performing a form of event study analysis based on sharp changes close to the time of moving. Denoting the number of years since last move by \( s \) (“event time”), we consider the following specification

\[
\log c_{is} = \sum_{s=0}^{21} \alpha_s Move_{is} + X_{is} \beta + \mu_q + \nu_{is},
\]

(23)

where \( c_{is} \) is spending in moving-related categories by household \( i \) who moved between \( s \) and \( s + 1 \) years ago, \( Move_{is} \) is an indicator for household \( i \) moving between \( s \) and \( s + 1 \) years ago, \( X_{is} \) is a vector of controls (log income, baby in the household, family size, age of the household head, and marital status), \( \mu_q \) are quarter-of-interview fixed effects, and \( \nu_{is} \) is a residual clustered by quarter of interview.

Figure 13 shows the \( \alpha_s \)-coefficients with 95% confidence intervals estimated from equation (23). Panel A pools all years, while panel B restricts the sample to years with low housing market activity (2001–03 & 2007–12). The two panels show a large and sharp effect on spending in year 0, a more modest effect on spending in year 1, and very small and mostly insignificant effects in all other years. The moving effects are smaller during recessions, but not by very much. While we cannot control for within-individual shocks that affect spending (absent panel data), the sharpness of spending effects in year 0-1 tend to rule out serially correlated confounders (such as job switches or promotions that change income permanently) as they would change spending levels beyond year 0 and 1. Our estimates imply that moving triggers a spending increase of at least 140% in the year of moving and 50% in the subsequent year.\(^40\)

Two robustness checks are worth considering. First, the estimates in Figure 13 represent average effects in the population, but the stamp duty stimulus targeted the lower end of the house price distribution where effects might be different. While the LCFS data does not contain information on house prices, we can look at heterogeneity by income as a proxy for house price heterogeneity. Appendix Figure B.5 shows that the log effects (\( \hat{\alpha}_0 \) and \( \hat{\alpha}_1 \)) are larger for households with lower income, consistent with the presence of a fixed cost element in moving-related expenditures. Hence, by using estimates of average moving-related spending (in percentages), we are being conservative in our estimates of the stimulus’ impact on spending.

Second, a potential concern is that moving-related spending (e.g. renovations) merely crowds out other forms of spending (e.g. restaurant visits) so that total consumer spending is not larger

\(^{40}\) These numbers are based on the estimates \( \hat{\alpha}_0 = 0.86 \) and \( \hat{\alpha}_1 = 0.40 \) from the event study regression restricting the sample to years with low housing market activity.
when moving.\footnote{To address this concern, Figure B.6 in the appendix repeats the event study analysis using total consumption rather than only explicitly moving-related consumption. We still see a very sharp increase in spending in year 0, but no longer in year 1. That is, households who are still incurring moving-related expenditures the year after moving (primarily renovations as discussed above) may be offsetting this with lower consumption in other categories. Hence, a conservative approach to estimating the spending effect of the stamp duty holiday is to only include moving-related spending in year 0.\footnote{Besides affecting moving-related spending via the number of movers, the stimulus policy may also affect spending on repairs and improvements conditional on moving. First, sellers who would normally sell their house for a price just above £175,000 may reduce spending on improvements to remain below the £175,000 notch. Second, sellers who would normally sell for just below £125,000 may increase spending on improvements as they no longer have to avoid the £125,000 notch. Third, all households buying in the range £125,000-£175,000 pay less tax and may increase spending on repairs and improvements conditional on moving.}} To address this concern, Figure B.6 in the appendix repeats the event study analysis using total consumption rather than only explicitly moving-related consumption. We still see a very sharp increase in spending in year 0, but no longer in year 1. That is, households who are still incurring moving-related expenditures the year after moving (primarily renovations as discussed above) may be offsetting this with lower consumption in other categories. Hence, a conservative approach to estimating the spending effect of the stamp duty holiday is to only include moving-related spending in year 0.\footnote{We calculate \( \phi \) based on the log coefficients from the event studies (\( \hat{\beta}_0 \) alone or \( \hat{\alpha}_0, \hat{\alpha}_1 \) together) evaluated at the average spending of people who moved more than 2 years ago (\( \mu_{2+} \)) and scaled by the average house value in the period (\( v^M = \£230,000 \)). We then add in the estate agents’ fees (1.98\%) and other fees (1.24\%) to arrive at \( \phi = (\exp(\hat{\alpha}_0) - 1 + \exp(\hat{\alpha}_1) - 1) \cdot (\mu_{2+}/v^M) + 1.98 + 1.24 \) (when including both the year-0 and year-1 effects).}

Combining these estimates with our earlier estimates of the impact of the stimulus policy on residential housing transactions (moving), we are able to assess the amount of spending generated by each dollar of foregone tax revenue. Denoting our estimate of moving-related spending as a fraction of the house value by \( \phi \), the impact of the stimulus policy on spending is \( \Delta C = \phi v^m \Delta n \) where \( v^m \) is the average value of houses bought due to the stimulus, and \( \Delta n \) is the number of additional houses bought due to the policy. The foregone tax revenue is given by \( \Delta Tax = \tau v^m n \), where \( \tau = 0.01 \) is the pre-stimulus tax rate and \( n \) is the counterfactual number of transactions in the price range affected by the stimulus. From our difference-in-differences analysis in the previous section, we have an estimate of \( \beta_H \approx \Delta n / n \), and so we can estimate the effect on spending per dollar of tax cut as \( \Delta C / \Delta Tax = \phi \beta_H / \tau \).

The results are shown in Table 3. Panel A of the table provides a range of estimates of \( \phi \) from the event study analysis, while Panel B provides a range of tax multipliers \( \phi \beta_H / \tau \) using different values of \( \phi \) and \( \beta_H \). The tax multipliers are around 1 or slightly higher. Our preferred multiplier is based on the bunching-adjusted estimate of \( \beta_H (= 0.20) \) and a conservative spending parameter \( \phi \) based on the year-0 effect alone, a full set of controls, and low-activity years (\( \phi = 5.09 \)). This gives an estimate of the spending effect per dollar of tax cut equal to 1.02. As a robustness check, Table B.1 reports tax multipliers using \( \phi \) estimates based on total consumption. Reassuringly, the estimates are very similar when including only the year-0 effect, with our preferred specification giving a multiplier of 1.10.

\footnote{The effect could also go the other way: moving house may increase spending in categories that are not explicitly moving-related as households are induced to re-optimize in various dimensions (say, buy a new car or bicycles for the kids).}
These estimates suggest that the stamp duty holiday was not only successful in stimulating housing market activity, but also provided a significant boost to real economic activity through the strong complementarities between moving house and consumer spending. These estimates exclude other indirect effects, for example labor market effects of increased mobility and Keynesian multiplier effects. As a benchmark, the previous work cited above on fiscal stimulus through income tax rebates found significantly smaller effects on consumer spending (0.2–0.7 dollars of spending per dollar of tax cut, as opposed to 1.02 dollars of spending here). Overall, our findings suggest that transaction tax cuts (or subsidies) can be very effective at stimulating both housing market activity and real economic activity during downturns.

6 Conclusion

This paper has studied the impact of housing transaction taxes based on administrative stamp duty records and quasi-experimental variation from notches and stimulus. We have shown that the housing market responds very strongly and quickly to transaction taxes across a range margins, making such taxes very distortionary compared to standard recurrent taxes. We have interpreted our results in the context of a housing model with downpayment constraints (building on Stein 1995), arguing that the liquidity and leverage channels amplify behavioral responses to transaction taxes and provides a natural explanation for the large behavioral responses we find.

Our most important and novel findings are those related to the 2008–2009 stamp duty holiday. These findings contribute to the large macro literature on fiscal stimulus, presenting some of the first evidence on the effectiveness of using temporary tax changes to stimulate the housing market during economic downturns. Our stimulus analysis carries two qualitative lessons. First, stimulating transactions of existing houses may have real effects due to the complementarities between moving house and spending. These complementarities combined with the large effect of transaction taxes on transaction volume create a direct tax multiplier of about 1, the same as one would get for spending multipliers. This is important for policy because tax stimulus has political and practical advantages over spending stimulus, because of the aversion to spending increases and the fact that the implementation of spending projects can have considerable time lags. For these reasons, US stimulus over the Great Recession had a much larger weight on tax stimulus than on spending stimulus, including a first-time homebuyer tax credit similar in spirit to the transaction tax cut analyzed here.

Second, our findings provide a stark counter-example to Mian & Sufi (2012), who find complete and swift reversal following the Cash-for-Clunkers stimulus program in the US. This suggests that any emerging consensus that tax stimulus necessarily leads to fast and full reversal is premature. Why are the experiences from these two policies so different? Two differences stand out. One is that housing stimulus may work differently than car stimulus due to the amplifying role of downpayment constraints in the housing market as shown by our theoretical model. Of course, financial frictions are also present in car markets, but they may be more severe in housing markets.
and perhaps especially at the time of the Great Recession. The other difference relates to practical implementation. Mian & Sufi (2012) considered a very short (1 month) and unanticipated program that gave households very little time to respond.\textsuperscript{44} It seems natural that such a program only induced short-term intertemporal substitution by households who were already planning to buy a new car in the near future. As shown by our (frictionless) model, a temporary price subsidy should create some extensive margin effect in addition to short-term intertemporal substitution. However, when allowing for optimization frictions in responses to short-term price changes, it is possible that the Cash-for-Clunkers program was over too quickly to trigger an extensive margin effect. Hence, our findings highlight the importance of the length of the stimulus program. More generally, our paper suggests the need for more work studying the details of program design and implementation that make stimulus effective.

Our analysis also implies that (permanent) housing transaction taxes are bad for long-run welfare. There are three reasons for this. First, the standard efficiency effect of taxes is given by the fiscal externality of behavioral responses and is proportional to the size of behavioral elasticities (see e.g. Feldstein 1999; Kleven & Kreiner 2005, 2006; Hendren 2015). This would be the entire efficiency effect of transaction taxes in an efficient housing market (Best & Kleven 2014) and it remains as one of the effects in an inefficient housing market. The fact that we find large elasticities of transaction volume implies that the fiscal externality is large. Second, in a market with downpayment constraints, both transaction volume and housing demand among constrained movers are below their first-best levels even without transaction taxes. These pre-existing distortions exacerbate the negative welfare effect of transaction taxes. Third, if other transaction costs of moving (such as commissions to real estate agents and lawyers) do not reflect true social costs, they act as additional tax wedges that make the welfare costs of imposing transaction taxes even larger.\textsuperscript{45} Fixed commissions tend to be large—in many countries larger than transaction taxes—and our estimates are potentially informative of the (distortionary) impact of such commissions. Note that the second and third effects imply that the optimal long-run transaction tax is negative, opposite real world policies. Our stimulus findings suggest that the optimal dynamic policy may be a variable subsidy, which is increased during busts and reduced during booms.

Finally, our study of transaction taxes in the property market contributes to the scant evidence on the effects of transaction taxes in asset markets more broadly, including the financial transaction taxes that have been discussed widely in recent years. An interesting question there turns on the ability of such taxes to affect the emergence of asset-price bubbles and the volatility of the economy more generally. Addressing this issue raises some daunting empirical challenges, ideally requiring exogenous variation in transaction taxes across economies, and so is left for future research.

\textsuperscript{44}The program was signed into law on June 24 of 2009 (with little prior public debate about the program) and was effective between July 24 – August 24.

\textsuperscript{45}Consistent with this idea, Hsieh & Moretti (2003) provide evidence that fixed commissions to real estate agents in the US (which are considerably higher than in the UK) create social inefficiencies.

Notes: The table shows how the stamp duty land tax schedule for residential property has varied over time. Each column represents a time period during which the tax schedule was constant. The rows represent price ranges, and the entry in each cell is the tax rate that applies to that price range in the time period.

| Impact of Moving on Spending | 4.99   | 1.03   | 6.01    |        |        |          |

Notes: The table shows the moving-related spending by movers in the 2001-2013 rounds of the Living Costs and Food Survey (LCFS) (excluding the 2008 round in which the housing tenure variable is corrupted). Panel A shows spending in 5 moving-related categories and total spending on all 5 categories. Column 1 shows spending by households who moved within the last year, column 2 shows households who moved between 1 and 2 years ago, and column 3 shows households who moved over 2 years ago. Column 4 shows the difference between spending by households who moved in the last year and those who moved over 2 years ago (subtracting column 3 from column 1). Column 5 shows the difference between spending by households who moved between 1 and 2 years ago and those who moved over 2 years ago (subtracting column 3 from column 2). Column 6 adds columns 5 and 6. Panel B shows moving-related spending as a fraction of the value of the house. The Total Spending row shows the last row of panel A as a fraction of the average house price (£230,000). Estate agents’ fees average 1.8% of the house price before VAT, or 1.98% with VAT (see http://www.which.co.uk/news/2011/03/estate-agents-fees-exposed-248666/). ReallyMoving (2012) estimates that other commissions and fees total £1,880 on average, and do not vary much with house value, so we scale this by the average value of houses bought in the range affected by the policy (£152,000).

Notes: The table shows the spending effects of the stamp duty holiday using only the moving-related spending categories listed in Table 2. Panel A shows the impact of moving on spending $\phi$ (% of house value) as implied by our different event-study specifications, while Panel B shows estimates of tax multipliers — spending effect per dollar of tax cut — given by $\phi \beta_H / \tau$. We calculate $\phi$ based on the log coefficients from the event studies ($\hat{\alpha}_0$ alone or $\hat{\alpha}_0$, $\hat{\alpha}_1$ together) evaluated at the average spending of people who moved more than 2 years ago ($\mu_{2+}$) and scaled by the average house value in the period ($v_M = £230, 000$). We then add in the estate agents' fees (1.98%) and other fees (1.24%) to arrive at $\phi = (\exp(\hat{\alpha}_0) - 1 + \exp(\hat{\alpha}_1) - 1) \cdot (\mu_{2+} / v_M) + 1.98 + 1.24$ (when including both the year-0 and year-1 effects). The columns labeled Year 0 use only $\hat{\alpha}_0$ while the columns labeled Year 0 + 1 use both $\hat{\alpha}_0$ and $\hat{\alpha}_1$. The columns labeled Controls include controls for log income, baby in the household, family size, age of the household head and marital status. The rows labeled Low Activity Years use only data from 2001-2003 and 2007-2012.
Figure 1: Theoretical Figures

A: Budget Set Diagram (Low $k$)  
B: Budget Set Diagram (Intermediate $k$)

C: Budget Set Diagram (High $k$)  
D: Predicted Observed Density

Notes: Figure 1 illustrates the implications of a notched transaction tax schedule in budget set diagrams (Panels A–C) and a density distribution diagram (Panels D). The budget set diagrams depict preferences as in equation (2) and the budget set in $(v,c)$-space for three values of initial debt $k$ to illustrate intensive responses for heterogeneous preferences $A$, but a specific demand elasticity $\varepsilon$. The notch creates bunching at the cutoff $\bar{v}$ by all individuals in a preference range $(\bar{A}, \bar{A} + \Delta \bar{A})$, who would have bought houses on the segment $(\bar{v}, \bar{v} + \Delta \bar{v})$ in the absence of the notch. The marginal bunching individual at $\bar{v} + \Delta \bar{A}$ is indifferent between $\bar{v}$ and the best interior location $v^I$. For low values of $k$ (Panel A) neither $v^I$ nor the counterfactual choice $\bar{v} + \Delta \bar{v}$ are downpayment constrained. For intermediate values of $k$ (Panel B), $v^I$ is downpayment constrained to equal $v^c (k, \tau + \Delta \tau)$, but not $\bar{v} + \Delta \bar{v}$. For high values of $k$ (Panel C), both $v^I = v^c (k, \tau + \Delta \tau)$ and $\bar{v} + \Delta \bar{v} = v^c (k, \tau)$ are downpayment constrained. For each parameter vector $\{\varepsilon, k, \gamma\}$ the range $(\bar{v}, v^I)$ will be empty, with the width of the range depending on the size of the demand elasticity $\varepsilon$ (and converging to zero for $\varepsilon = 0$). In addition to intensive responses, the notch creates extensive responses above $\bar{v}$ by individuals close to indifference between moving and not moving ($k \approx k_2$, where $k_2$ is defined in equation (6)). However, such extensive responses will be negligible just above the cutoff: if an individual prefers buying a house slightly above $\bar{v}$ in the absence of the notch, then he will be better off buying a house at $\bar{v}$ than not buying at all in the presence of the notch. Combining these effects, the observed density is predicted to be as illustrated in Panel D.
Notes: Figure 2 shows the stamp duty land tax schedule for residential properties in place in March 2013 graphically as the solid blue line. The tax liability jumps discretely at the notches at £125,000, £250,000, £500,000, £1,000,000 and £2,000,000. Within the brackets defined by these notches, the tax rate is constant, and applied to the whole transaction price at the rates shown along the top of the figure.
FIGURE 3: SUMMARY STATISTICS

A: Number of Transactions

B: Average Price

Notes: Panel A shows the monthly average price of property transactions relative to the average price in April 2005 in London (blue circles) and the U.K. (orange crosses). The average price of property transactions in London during the period April 2005 - October 2012 was £345,360 and the average price in the U.K. during our data period was £199,479. Panel B shows the monthly total number of property transactions relative to the number that took place in April 2005 in London (blue circles) and the U.K. (orange crosses). The average monthly number of property transactions in London during the period April 2005 - October 2012 was 12,955 while the average monthly number of property transactions in this period in the U.K. was 103,561.
Notes: The figure shows the observed density of property transactions (blue dots) and our estimated counterfactual density (red line) around the notch at £250,000 where the tax liability jumps by £5,000 (from 1% to 3% of the transaction price) in panel A; and around the notch at £500,000 where the tax liability jumps by £5,000 again (from 3% to 4% of the price) in panel B. The data used for these estimates excludes transactions that claim relief from the stamp duty land tax (except for those claiming first-time buyers’ relief) as the regular tax schedule does not apply to these transactions. The counterfactual density is estimated as in equation (20), using bins £100 wide and a polynomial of order 5. The vertical dashed lines denote the upper and lower bounds of the excluded region around the notch. The upper bound of the excluded region is chosen as the point where the observed density changes slope from positive to negative. The polynomial controls for round number bunching at multiples of £500, £1,000, £5,000, £10,000, £25,000 and £50,000. Both the empirical and the counterfactual density are shown aggregated up to bins £5,000 wide. $b$ is our estimate of the excess mass just below the notch scaled by the average counterfactual frequency in the excluded range, with its standard error shown in parentheses. $m$ is our estimate of the missing mass above the notch scaled by the average counterfactual frequency in the excluded range, with its standard error shown in parentheses. $m-b$ is our estimate of the difference between the missing mass and the bunching mass, again with its standard error shown in parentheses. The figures also show the average house value change created by the notch $\Delta \bar{v}$, and the tax liability change at the notch $\Delta Tax$. All standard errors are obtained by bootstrapping the procedure 200 times.
**Figure 5: Bunching and Holes Around the Lower Notch**

Notes: The figure shows the observed density of property transactions (blue dots) and our estimated counterfactual density (red line) around the lower notch in the residential property tax schedule where the tax liability jumps from 0 to 1% of the transaction price. The notch is at £60,000 in panel A; £120,000 in Panel B; £125,000 in panels C & E, and £175,000 in panel D. The notch was moved on 17 March 2005, 23 March 2006, 3 September 2008, and 1 January 2010. The data used for these estimates excludes transactions that claim relief from the stamp duty land tax (excepting those who claimed first time buyers’ relief) as the regular tax schedule does not apply to these transactions. The counterfactual is estimated as in equation (20), using bins £100 wide and a polynomial of order 5 in panels A, C, D and E and of order 4 in panel B. The vertical dashed lines denote the upper and lower bounds of the excluded region around the notch. The upper bound of the excluded region is chosen as the point where the observed density stops increasing and becomes decreasing (apart from spikes at round numbers). The polynomial controls for round number bunching at multiples £500, £1,000, £5,000, £10,000, £25,000 and £50,000. Both the empirical and the counterfactual density are shown aggregated up to bins £5,000 wide. $b$ is our estimate of the excess mass just below the notch scaled by the counterfactual density at the notch, with its standard error shown in parentheses. $m$ is our estimate of the missing mass above the notch scaled by the counterfactual density at the notch, and $m - b$ is our estimate of the difference between the missing mass and the bunching mass. The figures also show the average house value change created by the notch $\Delta \bar{v}$, and the tax liability change at the notch $\Delta \text{Tax}$. All standard errors are obtained by bootstrapping the procedure 200 times.
Notes: The figure shows our estimates of $b(\bar{v})$, the bunching mass just below $\bar{v}$ scaled by the counterfactual frequency at $\bar{v}$, by month from January 2007 to August 2011 and for two values of $\bar{v}$, £125,000 (blue circles) and £175,000 (orange crosses). The first vertical line is at September 2008 when the stamp duty holiday was unexpectedly announced, moving the notch from £125,000 to £175,000. The dashed vertical line is at December 2008 to represent the typical lag of up to 90 days to conclude transactions, leading to inertia in bunching responses. The second vertical line is at December 2009 when the stamp duty holiday came to an end as anticipated, moving the notch from £175,000 back to £125,000.
Notes: The figures show the weekly number of transactions around the end of the stamp duty holiday on 31 December 2009. Panel A shows the number of transactions taking place between 2009w27 and 2010w26 in the treated price range £125,000 – £175,000 (blue circles) alongside the number of transactions in the price ranges £75,000 – £125,000 (orange crosses) and £175,000 – £225,000 (green diamonds). Panel B shows the number of transactions taking place in the treated price range (£125,000 – £175,000) around the end of the stamp duty holiday, 2009w27 to 2010w26 (blue circles) as well as 1 year earlier (orange crosses) and 2 years earlier (green diamonds). Panel C shows the same price ranges as in panel A, but using data from 1 year earlier. Similarly, panel D shows the same price ranges as in panel A, but using data from 2 years earlier. The solid vertical line is placed at the end of the year (which at the end of 2009 is the end of the stamp duty holiday) and the dashed vertical lines demarcate the last 3 weeks of the year and the first 10 weeks of the year, which are the excluded range for the counterfactual estimates. The counterfactual is estimated according to (21):

\[
c_w = \sum_{j=0}^{7} \beta_j (z_w)^j + \eta I\{w \in \text{end of month}\} + \sum_{k=w^-}^{w^+} \gamma_k I\{w = k\} + \mu_w
\]

where \(c_w\) is the number of transactions in week \(w\) and \(z_w\) is the distance of week \(w\) from the end of 2009. The second term is a fixed effect for weeks at the end of the month (which feature heavier trading in every month), while the third term excludes weeks in the excluded range \((w^-, w^+)\). Each picture shows the difference-in-bunching estimate corresponding to the choice of treatment (blue circles) and control groups (orange crosses and green diamonds) depicted in the picture. The DiD estimate is the difference between the (normalized) bunching in the treatment group and the average bunching in the two control groups.
Figure 8: Effects of the Stamp Duty Holiday Stimulus: Naive Diff in Diff

Notes: The figure shows how the level of housing market activity changed over time in the price range affected by the stamp duty holiday (£125,000 - £175,000) and the neighbouring price range £175,000 - £225,000. The figure shows the normalized log monthly number of transactions defined as the log of the number of transactions in that month minus the average of the log of the number of transactions in the 24 months leading up to the start date of the Stamp Duty Holiday (September 2006 - August 2008).
FIGURE 9: EFFECTS OF THE STAMP DUTY HOLIDAY STIMULUS: DIFF IN DIFF WITH WIDER TREATMENT RANGE

Notes: The figure shows the effect of the stamp duty holiday stimulus on market activity using £115,000 - £195,000 as the treated price range (blue circles) and £195,000 - £235,000 as the control range (orange crosses). Panel A shows the log monthly number of transactions normalized by subtracting the average log number of transactions in the 24 months leading up to the stamp duty holiday (September 2006 - August 2008). We also show estimates of $\beta_H$, $\beta_R$ and $\beta_P$ from equation (22) with standard errors clustered by £5,000 bin to account for serial correlation (Bertrand et al. 2004). Panel B shows the differences between the monthly counts in panel A. Panel C shows the cumulative sum of the normalized log counts in panel A (blue dots and orange crosses) and the cumulative sum of the differences in panel B (green diamonds). Panel D shows how the proportion of the effect of the stamp duty holiday that is undone by reversal changes as we vary the end date of the reversal period. i.e. it shows $(\beta_R\Sigma_t Rev_t) / (16\beta_H)$ For different end dates of the period defining Reversal. The vertical line is our preferred choice for the first month of Post_t, January 2011, giving an estimate of the proportion of the effect undone by reversal of 0.42 (0.234).
Notes: The figure shows the effect of the stamp duty holiday stimulus on housing market activity using £125,000 - £175,000 as the treated price range and £175,000 - £225,000 as the control price range, but adjusting all counts for price manipulation using bunching estimates by moving excess transactions at £125,000 to prices between £125,000 and £150,000 and moving excess transactions at £175,000 to prices between £175,000 and £200,000. Panel A shows the log monthly number of transactions normalized by subtracting the average log number of transactions in the 24 months leading up to the stamp duty holiday (September 2006 - August 2008). We also show estimates of $\beta_H$, $\beta_R$ and $\beta_P$ from equation (22) with standard errors clustered by £5,000 bin to account for serial correlation (Bertrand et al. 2004). Panel B shows the differences between the monthly counts in panel A. Panel C shows the cumulative sum of the normalized log counts in panel A (blue dots and orange crosses) and the cumulative sum of the differences in panel B (green diamonds). Panel D shows how the proportion of the effect of the stamp duty holiday that is undone by reversal changes as we vary the end date of the period defining $Rev_t$. The vertical line is our preferred choice for the first month of $Post_t$, January 2011, giving an estimate of the proportion of the effect undone by reversal of 0.31 (0.119).
Notes: The figure shows a series of placebo estimates of the holiday effect $\beta_H$ in an extended version of the difference in difference regression (22) where we allow each 10K price bin between £115,000-£375,000 to be a separate treatment group and use the £375,000-£425,000 range as the control group. While the estimates in the treated range £125,000-£175,000 are positive and strongly significant, the placebo estimates in other price ranges are consistently close to zero and almost always statistically insignificant, supporting the identification strategy.
Notes: The figure shows the differences in spending on moving-related categories (repairs and improvements, removals, furniture, appliances, and commissions) between recent movers and those who moved more than 2 years ago separately for each round of the Living Costs and Food Survey (LCFS) from 2001/02 to 2013. The grey triangles show the difference between households who moved within the last year and those who moved more than 2 years ago. The black circles show the spending by those who move within the last year plus those who move between 1 and 2 years ago, minus the spending of those who moved more than 2 years ago.
Notes: The figure shows the estimated $\hat{\alpha}_s$ coefficients on spending by movers in different years from two estimates of our event study specification (23) along with their 95% confidence intervals. The event study compares log spending on categories related to moving by households with different move dates, controlling for income, household size, age and marital status of the household head, the presence of babies in the household, and quarter of interview fixed effects. Panel A shows the estimates pooling all available years 2001-2013 except 2008 (when the housing tenure data is corrupted) and panel B shows the estimates using only years with low housing market activity (2001-2003 and 2007-2012).

Figure 13: Event Studies of Household Spending Around Moving
A Proof of Proposition 5

First consider the households’ period-1 choice. Households who are induced to move in period 1 are those who do not satisfy condition (16) under \( \tau_1 \), but do satisfy this condition under \( \tau_1 - d\tau_1 \). For them,

\[
\left( u_1 (c_1^*, h_1^* (\tau_1, \tau_2)) + \delta V (h_1^* (\tau_1, \tau_2), Rk_2^*) \right) < \left( u_1 (y_1 - s_1, 1) + \delta V (1, R (k_1 - s_1)) \right) \leq \left( u_1 (c_1^*, h_1^* (\tau_1 - d\tau_1, \tau_2)) + \delta V (h_1^* (\tau_1 - d\tau_1, \tau_2), Rk_2^*) \right),
\]

where we make it explicit at which tax rates \( h_1^* (\cdot) \) is evaluated (but keep it implicit elsewhere). In terms of moving costs \( q_1 \) and debt \( k_1 \), these new period-1 movers satisfy

\[
\begin{align*}
\bar{q}_1 (\tau_1, \tau_2) &< q_1 \leq \bar{q}_1 (\tau_1 - d\tau_1, \tau_2) \tag{24} \\
\text{and/or} \quad k_1^2 (\tau_1, \tau_2) &< k_1 \leq k_1^2 (\tau_1 - d\tau_1, \tau_2). \tag{25}
\end{align*}
\]

Among the households satisfying (24)-(25), consider the period-2 choice. Households experiencing the timing effect are those who satisfy (15) under \( \tau_1 \), but do not satisfy it under \( \tau_1 - d\tau_1 \). These households satisfy

\[
u_2 (y_2 - R (k_1 - s_1), 1) \leq u_2 (c_2^*, h_2^*) < u_2 (y_2 - Rk_2^*, h_1^* (\tau_1 - d\tau_1, \tau_2)). \tag{26}\]

For them, \( q_2 \leq \bar{q}_2 (\tau_1, \tau_2) \) and \( Rk_2 = R (k_1 - s_1) \leq \bar{k}_2^2 (\tau_1, \tau_2) \), but either \( q_2 > \bar{q}_2 (\tau_1 - d\tau_1, \tau_2) \) or \( Rk_2^* > \bar{k}_2^2 (\tau_1 - d\tau_1, \tau_2) \).

Two types of households experience the extensive margin effect. First, some households do not move in period 2 with or without the tax cut, i.e.

\[
u_2 (c_2^*, h_2^*) < \min \{ u_2 (y_2 - R (k_1 - s_1), 1), u_2 (y_2 - Rk_2^*, h_1^* (\tau_1 - d\tau_1, \tau_2)) \}. \tag{27}\]

For them, we have \( q_2 > \bar{q}_2 (\tau_1, \tau_2) \) or \( Rk_2 = R (k_1 - s_1) > \bar{k}_2^2 (\tau_1, \tau_2) \) as well as \( q_2 > \bar{q}_2 (\tau_1 - d\tau_1, \tau_2) \) or \( Rk_2^* > \bar{k}_2^2 (\tau_1 - d\tau_1, \tau_2) \). Second, some households move in period 2 with or without the tax cut, i.e.

\[
u_2 (c_2^*, h_2^* (\tau_2)) \geq \max \{ u_2 (y_2 - R (k_1 - s_1), 1), u_2 (y_2 - Rk_2^*, h_1^* (\tau_1 - d\tau_1, \tau_2)) \}. \tag{28}\]

For them, \( q_2 \leq \min \{ \bar{q}_2 (\tau_1, \tau_2), \bar{q}_2 (\tau_1 - d\tau_1, \tau_2) \} \), \( Rk_2 = R (k_1 - s_1) \leq \bar{k}_2^2 (\tau_1, \tau_2) \), and \( Rk_2^* \leq \bar{k}_2^2 (\tau_1 - d\tau_1, \tau_2) \).
B Online Appendix (Not For Publication)

B.1 Bounding \( ε \) Using Bunching in the Presence of Downpayment Constraints

As shown by Kleven & Waseem (2013), the relationship between bunching and the demand elasticity can be characterized by considering the marginal bunching household at \( A = \bar{A} + \Delta \bar{A} \). This household is indifferent between bunching at the notch \( \bar{v} \) and choosing its preferred house in the interior of the higher tax bracket \( v^I \). The indifference condition requires that

\[
1 + p - (1 + \tau + \Delta \tau) v^I - q + A \left( \frac{v^I}{pA} \right)^{1+1/\varepsilon} \frac{1}{1 + 1/\varepsilon} = 1 + p - (1 + \tau) \bar{v} - q + A \left( \frac{\bar{v}}{pA} \right)^{1+1/\varepsilon} \frac{1}{1 + 1/\varepsilon}. \tag{29}
\]

In our framework, this relationship is complicated by the possibility that the marginal bunching household is downpayment constrained, either in the interior location \( v^I \) with the notch, in the counterfactual location \( \bar{v} + \Delta \bar{v} \) without the notch, or in both locations. When initial debt levels are sufficiently low, the marginal bunching household is not downpayment constrained in either location, as depicted in panel A of Figure 1. In this case, our analysis of the marginal bunching household is exactly analogous to that in Kleven & Waseem (2013). Define \( v^u (\tau) = pA [p (1 + \tau)]^\varepsilon \) as the unconstrained choice under the tax rate \( \tau \). We can substitute \( v^I = v^u (\tau + \Delta \tau) \) into equation (29), use \( \bar{v} + \Delta \bar{v} = v^u (\tau) \) to substitute out \( A \), and rearrange terms to show that the indifference condition can be written as

\[
\frac{1}{1 + \Delta \bar{v} / \bar{v}} - \frac{1}{1 + 1/\varepsilon} \left[ \frac{1}{1 + \Delta \bar{v} / \bar{v}} \right]^{1+1/\varepsilon} - \frac{1}{1 + \varepsilon} \left[ 1 + \frac{\Delta \tau}{1 + \tau} \right]^{1+\varepsilon} = 0. \tag{30}
\]

With our estimate of the width of the bunching segment \( \Delta \bar{v} \) and the tax parameters \( \bar{v} \) and \( \Delta \tau / (1 + \tau) \), this condition gives a unique demand elasticity \( \varepsilon \).

However, if the marginal bunching household is downpayment constrained in the interior of the high tax bracket (\( v^I < v^u (\tau + \Delta \tau) \)) and/or in the absence of the notch (\( \bar{v} + \Delta \bar{v} < v^u (\tau) \)), we can no longer substitute out \( A \) and \( v^I \) in (29). Nevertheless, as the following lemma shows, the solution to (30) gives an upper bound on the absolute value of \( \varepsilon \).

Lemma 1. Consider the indifference condition of the marginal bunching household (29), which holds for \( v^I \leq v^u (\tau + \Delta \tau) \) and \( \bar{v} + \Delta \bar{v} \leq v^u (\tau) \). If \( p (1 + \tau) > 1 \) and \(-1 < \varepsilon < 0\), then the value of \( \varepsilon \) that solves (30) is weakly smaller than the value of \( \varepsilon \) that solves (29). The solution to equation (30) therefore provides an upper bound on the absolute value of \( \varepsilon \).

Proof. First, note that (29) is a continuous function of \( \varepsilon \), \( A \), and \( v^I \) everywhere except at \( \varepsilon = -1 \), where it is not defined. Second, note that the downpayment constraint gives the following relationships: \( v^I \leq v^u (\tau + \Delta \tau) \) \( \Rightarrow \) \( A \geq v^I p^{-1} [p (1 + \tau + \Delta \tau)]^{-\varepsilon} \) and \( \bar{v} + \Delta \bar{v} \leq v^u (\tau) \) \( \Rightarrow \) \( A \geq (\bar{v} + \Delta \bar{v}) p^{-1} [p (1 + \tau)]^{-\varepsilon} \). Third, note that the value of \( \varepsilon \) that solves (30) equals the value that solves (29) when these relationships hold with equality. Combining these three points, it follows that it suffices to show that the solution to (29) features \( d\varepsilon / dv^I < 0 \) and \( d\varepsilon / dA > 0 \). To do this,
rewrite the indifference condition as

\[ IC = (1 + \tau + \Delta \tau) v^I - (1 + \tau) \bar{v} + \frac{A}{1 + \varepsilon} \left\{ \left( \frac{\bar{v}}{p} \right)^{1+1/\varepsilon} - \left( \frac{v^I}{p} \right)^{1+1/\varepsilon} \right\} = 0. \]  \hspace{1cm} (31)

Implicitly differentiating yields

\[ \frac{d\varepsilon}{dv^I} = -\frac{\partial IC}{\partial v^I} / \frac{\partial IC}{\partial \varepsilon} \quad \text{&} \quad \frac{d\varepsilon}{dA} = -\frac{\partial IC}{\partial A} / \frac{\partial IC}{\partial \varepsilon}. \]

To find \( \partial IC / \partial \varepsilon \) multiply and divide the last term of (31) by \( A \) and differentiate

\[ IC = (1 + \tau + \Delta \tau) v^I - (1 + \tau) \bar{v} + \frac{A}{1 + \varepsilon} \left\{ \left( \frac{\bar{v}}{pA} \right)^{1+1/\varepsilon} - \left( \frac{v^I}{pA} \right)^{1+1/\varepsilon} \right\}, \]

\[ \frac{\partial IC}{\partial \varepsilon} = \frac{A}{(1 + \varepsilon)^2} \left\{ \left( \frac{\bar{v}}{pA} \right)^{1+1/\varepsilon} - \left( \frac{v^I}{pA} \right)^{1+1/\varepsilon} \right\} - \frac{A}{1 + \varepsilon} \left[ \ln \left( \frac{\bar{v}}{pA} \right) \varepsilon - \ln \left( \frac{v^I}{pA} \right) \varepsilon^2 \right] \]

To sign the term in curly brackets, we follow the following steps. First, note that the terms in square brackets are the function \( x - \ln(x) \) evaluated at \( \left( \frac{\bar{v}}{pA} \right)^{1+1/\varepsilon} \) and \( \left( \frac{v^I}{pA} \right)^{1+1/\varepsilon} \). Second, differentiating, \( \partial (x - \ln(x)) / \partial x < 0 \) whenever \( x < 1 \). Third, since by definition \( v^I \) is the marginal buncher’s preferred choice in the high tax bracket, \( v^I > \bar{v} \). Fourth, since by assumption \( \varepsilon > -1 \), \( \left( \frac{\bar{v}}{pA} \right)^{1+1/\varepsilon} > \left( \frac{v^I}{pA} \right)^{1+1/\varepsilon} \). Fifth, since \( v^I \leq v^u (\tau + \Delta \tau) \) and \( \varepsilon < 0 \), it follows that \( v^I/pA \leq [p (1 + \tau + \Delta \tau)]^\varepsilon < 1 \) as long as \( p (1 + \tau + \Delta \tau) > 1 \), which we is implied by our assumption that \( p (1 + \tau) > 1 \). Sixth, since \( \bar{v} + \Delta \bar{v} \leq v^u (\tau) \) and \( \varepsilon < 0 \), it follows that \( \bar{v}/pA \leq [\bar{v} / (\bar{v} + \Delta \bar{v})] \left[ p (1 + \tau) \right]^\varepsilon < 1 \) as long as \( p (1 + \tau) > 1 \), which we have assumed. Combining these, the term in curly brackets is therefore negative. It therefore also follows that \( \partial IC / \partial \varepsilon < 0 \).

Straightforward differentiation also shows that

\[ \frac{\partial IC}{\partial v^I} = \frac{1}{p} \left[ p (1 + \tau + \Delta \tau) - \left( \frac{v^I}{pA} \right)^{1/\varepsilon} \right] \leq 0, \]

\[ \frac{\partial IC}{\partial A} = -\frac{1}{1 + \varepsilon} \left\{ \left( \frac{\bar{v}}{pA} \right)^{1+1/\varepsilon} - \left( \frac{v^I}{pA} \right)^{1+1/\varepsilon} \right\} < 0, \]

where signing the first derivative requires noting that the term in square brackets is the marginal cost of \( v \) minus the marginal utility of \( v \) evaluated at \( v^I \) and that for a liquidity constrained household the marginal utility of housing exceeds its marginal cost (otherwise the liquidity constraint would not bind). Combining the three derivatives and their signs yields the result.  \[ \square \]
The lemma provides an upper bound on $\varepsilon$ and a lower bound of 0 that always apply. However, we can also provide tighter bounds depending on whether liquidity constraints bind at $v'$ and/or at $\bar{v} + \Delta \bar{v}$. The marginal bunching household is never affected by liquidity constraints whenever their debt is low enough. In particular,

$$k < \min \{ \bar{k}_1 (\tau), \bar{k}_1 (\tau + \Delta \tau) \},$$  

(32)

where $\bar{k}_1 (\tau) = p [1 - Ap^\varepsilon (1 + \tau)^\varepsilon (\gamma + \tau)] - q$ is the debt level for which liquidity constraints start to bind in the counterfactual case ($\bar{v} + \Delta \bar{v} = v^u (\tau) = v^c (\tau)$) and similarly $\bar{k}_1 (\tau + \Delta \tau) = p [1 - Ap^\varepsilon (1 + \tau + \Delta \tau)^\varepsilon (\gamma + \tau + \Delta \tau)] - q$ is the debt level at which liquidity constraints start to bind in the high tax bracket ($v' = v^u (\tau + \Delta \tau) = v^c (\tau + \Delta \tau)$). Whenever $\varepsilon > -1$, $\bar{k}_1 (\tau + \Delta \tau) < \bar{k}_1 (\tau)$ and so any household that is liquidity constrained absent the notch is also liquidity constrained at its preferred point in the high tax bracket.

When $\bar{k}_1 (\tau + \Delta \tau) < k \leq \bar{k}_1 (\tau)$, we enter the case depicted in panel B of Figure 1 and the marginal bunching household is downpayment constrained at its best interior choice ($v' < v^u (\tau + \Delta \tau)$), but not at its no-notch location ($\bar{v} + \Delta \bar{v} = v^u (\tau)$). Since the marginal buncher is not downpayment constrained absent the notch, we can use $\bar{v} + \Delta \bar{v} = v^u (\tau) = pA [p (1 + \tau)]^\varepsilon$ to substitute out $A$ in (29) and rewrite the indifference condition as

$$\frac{1}{1 + \Delta \bar{v} / \bar{v}} - \left( 1 + \frac{\Delta \tau}{1 + \tau} \right) \left( \frac{v'}{\bar{v} + \Delta \bar{v}} \right) = \frac{1}{1 + 1/\varepsilon} \left[ \left( \frac{1}{1 + 1/\varepsilon} \right)^{1+1/\varepsilon} - \left( \frac{v'}{\bar{v} + \Delta \bar{v}} \right)^{1+1/\varepsilon} \right].$$  

(33)

With an estimate of the width of the bunching segment $\Delta \bar{v}$ and knowledge of the tax parameters $\bar{v}$, $\tau$ and $\Delta \tau$, equation (33) implicitly defines $\varepsilon$ as a function of $v'$. By lemma 1 we know that this solution features $d\varepsilon / dv' < 0$ and so bounds on $v'$ imply bounds on $\varepsilon$.

The condition $v' < v^u (\tau + \Delta \tau)$ gives us an upper bound on $v'$ and hence on the absolute value of $\varepsilon$. To get a lower bound on $v'$, we use the assumption that the household is not downpayment constrained absent the notch: $\bar{v} + \Delta \bar{v} = v^u (\tau) \leq v^c (\tau)$. Combining this with the definitions that $v^c (\tau) = (p - k - q) / (\gamma + \tau)$ and $v^c (\tau + \Delta \tau) = (p - k - q) / (\gamma + \tau + \Delta \tau) = v'$, we see that $v' \geq \frac{1}{1 + \Delta \bar{v} / \bar{v}} (\bar{v} + \Delta \bar{v})$, which gives us a lower bound on $v'$ and hence on the absolute value of $\varepsilon$. The lower bound on $\varepsilon$ is given by the solution to (33) when $v' = \frac{1}{1 + \Delta \bar{v} / \bar{v}} (\bar{v} + \Delta \bar{v})$:

$$\frac{1}{1 + \Delta \bar{v} / \bar{v}} - \frac{1 + \Delta \bar{v} / \bar{v}}{1 + \Delta \bar{v} / \bar{v}} + \frac{1}{1 + 1/\varepsilon} \left[ \frac{1}{1 + \Delta \bar{v} / \bar{v}} \right]^{1+1/\varepsilon} - \frac{1}{1 + 1/\varepsilon} \left[ \frac{1}{1 + \Delta \bar{v} / \bar{v}} \right]^{1+1/\varepsilon} = 0,$$  

(34)

requiring us to calibrate the value of $\gamma$.

Finally, when $k > \bar{k}_1 (\tau)$ the marginal bunching household is downpayment constrained both at $\bar{v} + \Delta \bar{v}$ without the notch and at $v'$ with the notch as depicted in panel C of Figure 1. In this case, we have that $v' = \frac{1}{1 + \Delta \bar{v} / \bar{v}} (\bar{v} + \Delta \bar{v})$ using $v' = v^c (\tau + \Delta \tau)$ and $\bar{v} + \Delta \bar{v} = v^c (\tau)$, but $\bar{v} + \Delta \bar{v} \leq v^u (\tau)$ only provides a lower bound on $A$. Since by Lemma 1 we have $d\varepsilon / dA > 0$, equation (34) gives us an upper bound on the absolute value of $\varepsilon$ and 0 is the lower bound.
B.2 Additional Figures & Tables

**Figure B.1: Bunching and Holes Around the Highest Notches**

**A: Notch at £1,000,000**

- \( b = 0.70 \)
- \( Dv = £30,000 \)
- \( DTax = £10,000 \)

**B: Notch at £2,000,000**

- \( b = 1.26 \)
- \( Dv = £100,000 \)
- \( DTax = £40,000 \)

Notes: The figure shows the observed density of property transactions (blue dots) and the density of property transactions in the year leading up to the introduction of the notch (red line) around the notches for very high value properties. The vertical dashed lines denote the upper and lower bounds of the excluded region around the notch. The upper bound of the excluded region is chosen as the point where the observed density changes slope from positive to negative. Panel A shows the notch at £1,000,000 introduced on 6 April 2011 where the tax liability jumps by £10,000 (from 4% to 5% of the transaction price) with both densities aggregated up to bins £25,000 wide. Panel B shows the notch at £2,000,000 introduced on 22 March 2012 where the tax liability jumps by £40,000 (from 5% to 7% of the transaction price) with both densities are aggregated up to bins £50,000 wide. \( b \) is our estimate of the excess mass just below the notch scaled by the average counterfactual frequency in the excluded range, \( Dv \) is the average house value change created by the notch, and \( DTax \) is the tax liability change at the notch.

Notes: The figure shows the observed density of property transactions (blue dots) and our estimated counterfactual density (red line) in the region £75,000 – £225,000 separately for each month. On 3 September 2008, the bottom notch was moved unexpectedly from £125,000 to £175,000. The estimation of the counterfactual is as described in section 4.1. The estimation excludes data in the regions £115,000 – 140,000 and £170,000 – £190,000 and uses a polynomial of order 5. Animated versions of the monthly bunching figures that show the dynamics vividly can be found on our websites, for example at [http://www.henrikkleven.com/uploads/3/7/3/1/37310663/best-kleven_landnotches_april2013_videos.pdf](http://www.henrikkleven.com/uploads/3/7/3/1/37310663/best-kleven_landnotches_april2013_videos.pdf)
Notes: The figure shows the observed density of property transactions (blue dots) and our estimated counterfactual density (red line) in the region £75,000 – £225,000 separately for each month. On 1 January 2010, the bottom notch was moved back from £175,000 to £125,000 as announced previously. The estimation of the counterfactual is as described in section 4.1. The estimation excludes data in the regions £115,000 – 140,000 and £170,000 – £190,000 and uses a polynomial of order 5. Animated versions of the monthly bunching figures that show the dynamics vividly can be found on our websites, for example at http://www.henrikkleven.com/uploads/3/7/3/1/37310663/best-kleven_landnotches_april2013_videos.pdf
**Figure B.4: Effects of the Permanent Reform: Adjusting for Bunching**

**A: Normalized Log Counts**

![Normalized Log Counts Graph]

**B: Cumulative Effect**

![Cumulative Effect Graph]

Notes: The figure shows the effect of the permanent tax cut of March 2005 when the bottom notch was moved from £60,000 to £120,000 on housing market activity using the price range £60,000 - £120,000 as the treated price range and £120,000 - £180,000 as the control price range. However, all counts are adjusted for price manipulation using bunching estimates by moving excess transactions at £60,000 to prices between £60,000 and £85,000 and moving excess transactions at £120,000 to prices between £120,000 and £145,000. Panel A shows the normalized log monthly number of transactions defined as the log of the number of transactions in that month minus the average of the log of the number of transactions in the 5 months leading up to the date of the reform (November 2004 - March 2005). Superimposed on that is our estimates of $\beta$ from the regression

$$n_{it} = \alpha_0 \text{Pre}_t + \alpha_1 \text{Post}_t + \alpha_2 \text{Treated}_i + \beta P \text{Post}_t \times \text{Treated}_i + \nu_{it}$$

where $n_{it}$ is the log of the monthly number of transactions $\text{Pre}_t$ is a dummy for the pre-period November 2004–March 2005 inclusive, $\text{Post}_t$ is a dummy for the months after the reform April 2005–March 2006 inclusive. $\text{Treated}_i$ is a dummy for the treated price range and finally $\nu_{it}$ is an error term. Panel B shows the cumulative sum of the normalized log counts in panel A (blue dots and orange crosses).
Figure B.5: Heterogeneity of Household Spending Effects by Income

Panel A: Lowest Income Tercile

Panel B: Highest Income Tercile

Notes: The figure shows the estimated $\hat{\alpha}_s$ coefficients on spending by movers in different years from two estimates of our event study specification (23) along with their 95% confidence intervals. The event study compares log consumption by households with different move dates, controlling for income, household size, age and marital status of the household head, the presence of babies in the household, and quarter of interview fixed effects. Panel A shows the estimates for the lowest income tercile (where the terciles are calculated separately for each round of the survey) and panel B shows the estimates for the highest income tercile. The effects are smaller for the higher income group.
Figure B.6: Event Studies Using Total Consumption

Panel A: All Years

Panel B: Low Activity Years

Notes: The figure shows the estimated $\hat{\alpha}$ coefficients on spending by movers in different years from two estimates of our event study specification (23) along with their 95% confidence intervals. The event study compares the log of total household spending (as opposed to just spending on categories related to moving, as in figure 13) by households with different move dates, controlling for income, household size, age and marital status of the household head, the presence of babies in the household, and quarter of interview fixed effects. Panel A shows the estimates pooling all available years 2001-2013 except 2008 (when the housing tenure data is corrupted) and panel B shows the estimates using only years with low housing market activity (2001-2003 and 2007-2012).

</tbody>
</table>

Notes: The table shows the spending effects of the stamp duty holiday using total consumption across all categories. Panel A shows the impact of moving on spending $\phi$ (% of house value) as implied by our different event-study specifications, while Panel B shows estimates of tax multipliers — spending effect per dollar of tax cut — given by $\phi \beta_H / \tau$. We calculate $\phi$ based on the log coefficients from the event studies ($\hat{\alpha}_0$ alone or $\hat{\alpha}_0$, $\hat{\alpha}_1$ together) evaluated at the average spending of people who moved more than 2 years ago ($\mu_{2+}$) and scaled by the average house value in the period ($v^M = £230,000$). We then add in the estate agents’ fees (1.98%) and other fees (1.24%) to arrive at $\phi = (\exp(\hat{\alpha}_0) - 1 + \exp(\hat{\alpha}_1)) \cdot (\mu_{2+}, v^M) + 1.98 + 1.24$ (when including both the year-0 and year-1 effects). The columns labeled Year 0 use only $\hat{\alpha}_0$ while the columns labeled Year 0 + 1 use both $\hat{\alpha}_0$ and $\hat{\alpha}_1$. The columns labeled Controls include controls for log income, baby in the household, family size, age of the household head and marital status. The rows labeled Low Activity Years use only data from 2001-2003 and 2007-2012.
